COMMITTEE OF CONSULTING EDITORS.

WALTER B. CANNON, M.D.
HARVEY CUSHING, M.D.
DAVID L. EDSALL, M.D.
REID HUNT, M.D.
ROGER I. LEE, M.D.

ALLAN J. McLAUGHLIN, M.D.
ROBERT B. OSGOOD, M.D.
MILTON J. ROSENAC, M.D.
EDWARD C. STREETER, M.D.
E. W. TAYLOR, M.D.

ADVISORY COMMITTEE.

EDWARD C. STREETER, M.D.
WALTER P. BOWERS, M.D.
HOMER GAGE, M.D.
JOEL E. GOLDSWORTHY, M.D.
LYMAN A. JONES, M.D.
ROBERT B. OSGOOD, M.D.
HUGH WILLIAMS, M.D.
ALFRED WORCESTER, M.D.

ABSTRACTORS OF CURRENT
LITERATURE.

JOHN BRYANT, M.D.
LAURENCE D. CHAPIN, M.D.
REGINALD FITZ, M.D.
CHANNING FROTHINGHAM, M.D.
TORE W. HAERER, M.D.
JOHN B. HAWES, 2D, M.D.
FOSTER S. KELLOGG, M.D.
ROGER I. LEE, M.D.
GEORGE A. LELAND, JR., M.D.
JAMES H. MEANS, M.D.
RICHARD H. MILLER, M.D.
FRANCIS W. PALFREY, M.D.
EDWARD H. RISLEY, M.D.
GEORGE G. SMITH, M.D.
LESLEY H. SPOONER, M.D.
WILDER TILESTON, M.D.
EDWARD L. YOUNG, JR., M.D.

REPORTERS OF PROGRESS.

A. E. AUSTIN, M.D.
JOHN BAPT BLAKE, M.D.
JOHN T. BOWEN, M.D.
EDMUND W. CLAP, M.D.,
ALGERNON COOLIDGE, M.D.
ROBERT L. DENORMANDIE, M.D.
ROGER I. LEE, M.D.
JOHN LOVETT MORSE, M.D.
H. P. MOSHER, M.D.
ROBERT B. OSGOOD, M.D.
STEPHEN RUSHMORE, M.D.
HENRY R. STEDMAN, M.D.
JOHN J. THOMAS, M.D.
PAUL THORNDIKE, M.D.
S. B. WOLBACH, M.D.

INDEX TO VOLUME CLXXIII.

AUTHORS.

- Aetion, A. F.** Tuberculosis work in this state, 241.
- Albee, F. H.** An electro-motor bone outfit and technic of its use, 273.
- Allen, F. M.** Note concerning exercise in the treatment of severe diabetes, 745.
- Anderson, H. M., and Bazeley, J. H.** Mental features of congenital syphilis, 952.
- Anderson, V. V.** A proper classification of borderline mental cases amongst offenders, 466.
- Austin, A. E.** Progress in biochemistry, 883.
- Ayer, J. B.** Neuroma of ulnar nerve: analysis of a case, 555.
- Ayer, J. B., and Barney, J. D.** An unusual case of obstructing prostate diagnosed with difficulty from tabs, 620.
- Barnes, H. A.** The radical treatment of peritonissular abscess by tonsillectomy during the acute stage of the disease, 994.
- Barney, J. D., and Ayer, J. B.** An unusual case of obstructing prostate diagnosed with difficulty from tabs, 620.
- Bazeley, J. H., and Anderson, H. M.** Mental features of congenital syphilis, 952.
- Boyditch, V. V.** The origin and aims of the Massachusetts Anti-Tuberculosis League, 225; What the general practitioner should know about incipient pulmonary tuberculosis, 795.
- Bowen, J. T.** Report on dermatology, 358.
- Bowers, W. P.** Reporting cases of tuberculosis, 235.
- Brackett, E. G., and Marshall, H. W.** Late results of operations upon hip joints for hypertrophic arthritis, 688.
- Brown, J. H., and Kilmington, A. R.** Technic of transfusion by means of glass tubes, 425.
- Brown, Lloyd T.** Fracture of the transverse processes of the fifth lumbar vertebra, 922.
- Brown, P.** The recognition of pleural disorders by x-rays, with special reference to empyema, 802.
- Bryant, J.** The carnivorous and herbivorous types in man: the possibility and utility of their recognition. II. Certain general considerations, 384; The use of calcium in the treatment of epilepsy, 547; Sunshine: its neglected analgesic-sedative action, 320.
- Bufford, J. H., and Dennie, C. C.** The bacterin treatment of certain chronic pyogenic dermatosis, 910.
- Burgess, A. M.** A method of testing gastric secretion by the use of a self-closing dredge, 581.
- Cabot, H.** Medicine—a profession or a trade, 685.
- Cheever, D.** Concerning traumatic rupture of the duodenal fistula: with the report of a case, 454.
- Christman, H. A.** The use of digitalis in the various forms of cardiac arrhythmia, 306.
- Cobb, F.** The surgical treatment of cancer of the cervix uteri, 85.
- Colby, J. M.** Massage and remedial exercises in the treatment of children's paralyses. Their differentiation in use, 696.
- Coriat, I. H.** Some new symptoms in amaurotic family idiocy, 20.
- Cottagen, F. J.** Pneumodynamics of empyema, 804; disinfection of septic joints, 905.
- Cones, W. P.** Luetic bursoptathy of Verneuil: Report of case of the congenital type, 18; Joseph Francols Malgaigne, 1806-1865, 699; Gummatus cervical adenitis: its relation to and mistaken diagnosis for tuberculous cervical adenitis, 777.
- Craithree, E. G.** A case of thrombophlebitis of the veins of the cord associated with colon bacillus infection of the epididymis, 705.
- Cronin, H. J.** The workmen's compensation act and the physician, 578.
- Davis, M. M.** Tuberculosis associations as health educators, 238.
- Davis, J. S.** Therapeutic value of injections of whole blood, 693.
- Dennie, C. C., and Bufford, J. H.** The bacterin treatment of certain chronic pyogenic dermatosis, 910.
- Denny, C. F. A.** Salvarsan apparatus, 961.
- Dodd, W. J., and Brown, L. T.** Fracture of the transverse processes of the fifth lumbar vertebra, 922.
- Dodd, W. J., Lee, R. I., and Young, E. L.** A study of the effect of rowing on the heart, 493.
- Dunham, F. L.** Medical inspection of school children, 240.
- Durant, C. E.** A brief consideration of acute pancreatitis. With case reports, 459.
- Edes, R. T.** Wanted—a fad, 948.
- Ehrenfried, A.** Local anesthesia in the radical cure of hernia, 780.
- Emerson, E. H.** Alcoholism, 113.
- Emerson, H.** The relation of the medical profession to preventive medicine, 603.
- Emerson, W. R. P.** Acute otitis media in infancy and early childhood: Avoidable mistakes in diagnosis, prevention, treatment, 616.
- Eastis, R. S.** Endocarditis in children: Its prophylaxis and treatment in an out-patient department, 348.
- Eastis, R. S., and Smith, R. H.** Report of progress in pediatrics, 125.
- Farlow, J. W.** Reply to an article by O. D. Phelps on a "Nob of the frenum of the upper lip," 746.
- Footle, J. S.** The femur of an idiopathic epileptic, 392.
- Gage, H.** Acute tubercular inflammation of the ileocolic glands simulating appendicitis, 301.
- Goadale, J. H.** Pollen therapy in hay fever, 42.
- Gosline, H. I.** Results of the treatment of pyorrhea alveolaris and allied conditions with eucetine hydrochloride at the Danvers State Hospital—preliminary report, 124.
- Graham, G. P.** Variations in the sensory threshold for faradic stimulation in psychopathic subjects, 198.
- Graham, C.** Notes on gastric and duodenal ulcers, 543.
- Gray, E. T.** A case of pyelonephritis, complicated by adeno-carcinoma and chyluria, 95.
- Greag, D. A.** Few economic facts of the syphilis problem, from the psychiatric side, 821.
- Greenough, H. B.** Report of Harvard University service at the American Ambulance, Lycee Pasteur, Neuilly-sur-Seine, France, 735.
- Gros, E. L.** The transportation of the wounded, 1.
- Haines, E. L.** The therapeutic value of occupation for the insane, 569.
- Hanson, W. T.** Scope of public health service, 337.
- Harrington, T. F.** The responsibility and opportunity of the teacher in preventing tuberculosis, 239.
- Hawes, J. H.** Errors in the diagnosis of chronic pulmonary disease, 850; The present situation in regard to local tuberculosis hospitals, 229.
- Hatch, J. A.** Leprosy and its relation to Massachusetts, 48.
- Howard, P. R.** A new method of treating flat-foot, 432.
- Hubbard, J. C.** Cholelithiasis: an argument for early operation, 457.
- Huntington, J. L.** The pregnancy clinic and the midwife: a comparison, 764.
- Hutchins, H. T.** Limitations of the radical operation for cervical cancer of the uterus, 97.
- Jarrett, M. C.** Estimate of the cost of social work in connection with examination and treatment of other members of families of syphilitic patients throughout the state, 821.
- Johnson, C. K.** The management of breast feeding, with case reports, 278.
- Joslin, E. P.** Pregnancy and diabetes mellitus, 841.
- Kantor, J. L., and Levy, I. H.** Study of a case of epidemic typhus fever imported into central New York, 473.
- Katsulinas, G. M.** The relation of leprosy to the community, 53.
- Keen, W. W.** The dangers of ether as an anesthetic, 831.
- Kelley, E. R.** Contagious diseases, 163.
- Kerr, R. B.** The present status of the anti-tuberculosis work in New Hampshire and some suggestions for the future, 263.
- Kilgore, E. S.** Clinical records in relation to teaching and research—a plan to promote conservation and utilization of material, 767.
- Kilmington, A. R., and Brown, J. H.** Technic of transfusion by means of glass tubes, 425.
- Klotz, W. C.** A study of Kroenig's isthmus in pulmonary tuberculosis, 877.
- Koefod, H. O., and Solomon, H. C.** The significance of changes in cellular content of cerebrospinal fluid in changes in cellular content of cerebrospinal fluid in changes in cellular content of cerebrospinal fluid in changes in cellular content of cerebrospinal fluid, 767.
- Koefod, H. O., Solomon, H. C., and Welles, E. S.** Diagnostic value of Lange's gold sol test, 955.

SUBJECTS.

- Abscess, Pulmonary.** Massachusetts Medical Society symposium on empyema and I. The medical aspects of empyema and pulmonary abscess, Frederick T. Lord, M.D., 789; II. The recognition of pleural disorders by x-rays, with special reference to empyema, Percy Brown, M.D., 802; III. Pneumodynamics of empyema, Frederic J. Cotton, M.D., 804; IV. The treatment of chronic empyema, F. B. Lund, M.D., 808; V. Lung abscess and bronchiectasis from a surgical point of view, certain end results of acute and chronic empyema, Wyman Whittemore, M.D., 811; the radical treatment of peritonissillar abscess by tonsillectomy during the acute state of the disease, Harry A. Barnes, M.D., 994.
- Accidents.** Some paralytic conditions resulting from surgical and obstetrical, James Warren Sever, M.D., 9.
- Acidosis, epidemic in children,** 923.
- Acute tubercular inflammation of the ileo-colic glands simulating appendicitis.**—Homer Gage, M. D., 301.
- Acute Pancreatitis.** A brief consideration of, with case reports, Charles E. Durant, M.D., 459.
- Adeno-Carcinoma.** A case of ptyelonephritis, complicated by, Elizabeth T. Gray, M.D., 95.
- Adenoid Operations.** Elimination of voice defects following, Walter B. Swift, M.D., 782.
- Admission to the State Tuberculosis Sanatoria,** 1006.
- Airways.** A successful treatment for acute infection of, Irving Wilson Voorhees, M.S., M.D., 702.
- Alcoholism.** Ernest B. Emerson, M.D., 113.
- Alpecia syphilitica,** Douglass W. Montgomery, M.D., 913.
- Amaurotic Family Idiocy.** Some new symptoms in, Isador H. Coriat, M.D., 20.
- American Academy of Medicine.** Annual meeting, 102.
- American Ambulance.** First impressions of the opportunity for orthopaedic work at, Robert B. Osgood, M.D., Boston, 7; Report of Harvard University Service at the American Ambulance, Lycee Pasteur, Neuilly-sur-Seine, France, Robert E. Greenough, M.D., 735.
- American College of Surgeons.** Meeting, 628.
- American Institute of Homeopathy.** Annual meeting, 103.
- American Medical Association.** Annual meeting, 102.
- Ancient remedies for hicough,** 335.
- Anesthesia, Local.** in the radical cure of hernia, Albert Ehrlich, M.D., 780; Some modern ideas about anesthesia, Frank L. Richardson, M.D., 943.
- Anterior Poliomyelitis.** A case of, with multiple paralyses, including the hitherto unrecorded involvement of the left diaphragm, Philip H. Sylvester, M.D., 428.
- Antiseptic.** A new, 563.
- Anti-Tuberculosis Work.** The present status of in New Hampshire and some suggestions for the future, Robert B. Kerr, M.D., 263.
- Antrum of Highmore.** Suction and irrigation apparatus for the diagnosis and treatment of, Joseph Penn, M.D., 432.
- Army.** Prevalence of syphilis in, 516.
- Arthritis.** Pneumococcic, with report of six cases, James Warren Sever, M.D., 387; Late results of operations upon hip joints or hypertrophic, E. G. Brackett, M.D., and H. W. Marshall, M.D., 688.
- Artificial Pneumothorax.** Edward O. Otis, M.D., 740.
- Auricular fibrillation and complete heart-block,** Paul Dudley White, M.D., 431.
- B. Dysenteriae.** A note on the invasion of the bodies of infants by, Carl TenBroeck, M.D., 284; The presence of *B. dysenteriae*, *B. proteus vulgaris*, bact. Welchii, and Morgan's bacillus No. 1, in the stools of cases of infectious diarrhea, Carl TenBroeck, M.D., and Frank Garm Norbury, 280.
- Bacterial treatment of certain chronic pyogenic dermatoses,** Charles C. Dennie, M.D., and John H. Bufford, M.D., 910.
- Belgian Physicians' relief fund,** 36, 74, 112, 150, 223, 300, 326, 371, 412, 450, 488, 525, 564, 602, 634, 910.
- Bellman.** Effects of selection on alkaloids, 683.
- Biochemistry.** Progress in, A. Everett Austin, M.D., 882.
- Birth Control.** Havelock Ellis and, 481; and dynamic evolution, 555.
- Birth Rate.** The menace of a declining, 517.
- Bladder Tumors.** in the young, R. F. O'Neil, M.D., 873.
- Blind, Whole.** Therapeutic value of injections of, J. Spencer Davis, M.D., 693.
- Blood-Letting.** The history of, 408.
- Blood Pressure.** Experimental and clinical observations on, in spinal anesthesia, George C. Smith, M.D., 502; Blood pressure, Cadis Phipps, M.D., 476; Blood Pressure determinations, urinary findings and differential blood counts in a group of 682 young male adults, Roger I. Lee, M.D., 541.

Addresses.

THE TRANSPORTATION OF THE WOUNDED.*

BY EDMUND L. GROS, M.D., PARIS, FRANCE.

Mr. President, colleagues, ladies and gentlemen:

I am to discuss today the question of transportation of the wounded, which is one of the problems of modern warfare—perhaps the greatest. Compared to the progress which has been made in perfecting the means of destruction there is no question that the methods of evacuating the wounded are certainly very crude and open to great improvement.

The advent of the automobile should have been the means of simplifying and ameliorating these methods and of making military sanitation equal to emergencies of modern war.

As we shall see, this has not been the case, because the railway is still the main medium of transport, and motor ambulances are not utilized to the extent that they should be.

One of the main reasons why the evacuation of the wounded is often so badly carried out is that the lines utilized for this transportation are often the same as those that are used for the conveyance of troops, food and ammunition. This has given rise to that implacable formula so often quoted, *Ammunition first, food second,*

wounded third. This, to my mind, is a cruel, senseless and useless maxim. How many human lives have been sacrificed to it!

The task of evacuating the wounded at its best is undoubtedly a complicated one for many reasons: There is no work which undergoes such unexpected and startling variations. On certain days, the number of wounded to be evacuated (as was the case some weeks ago) did not exceed 300 all along the French front, while again there may be 10,000 or 20,000, or even more, in a day, as in the battle of the Marne. What still further hampers the *Service de Santé* is that the greater the number of wounded at a given point the more difficult the evacuation becomes, because of the congestion of the various lines of transportation.

When one fully appreciates the tremendous difficulties which confront the military surgeon in his work at the front, one can but admire his courage, his devotion and his resource. Our experience in the transportation of the wounded teaches us that there is a vast difference between theory and practice. When one opens a book on the subject—"Troussaint's *Service de Santé en campagne*"—or any other treatise on the subject, one finds a great many precise rules and regulations dealing with the transportation and evacuation of the wounded. The handling of the wounded becomes apparently a question of military tactics. It would seem to be a very simple matter, but how different are the actual facts! There is no other service which is subject to so many daily and hourly variations and in which the conditions are so constantly changing.

We all know that there are three different

* Read before the Medical Society of the American Ambulance Hospital of Paris.

phases in the movements of an army or of a battalion: It may *advance, remain stationary, or retreat*. The various military operations are, of course, capable of all sorts of variations, any one of which may in a moment create for the Sanitary Service situations of the greatest difficulty.

If the army advances, the situation is very simple, because the wounded become each minute further removed from the enemy, and it is comparatively easy to handle them. When the army remains stationary, as in the present form of trench warfare, the situation is also very simple, because the Sanitary Service has ample time to organize its work.

But when the army is in retreat the difficulties begin. The enemy advances with more or less rapidity, and the *Postes de Secours* and the field hospitals must be evacuated without delay. Frequently the patients can be removed to the rear, but too often the evacuation cannot be effected rapidly enough, and the wounded must be left where they are in charge of one of the surgeons who remains behind. Many of them fall into the hands of the enemy.

These three phases have already been exemplified in this war:—

1. The retreat from the north after the battle of Charleroi.
2. The advance during the battle of the Marne.
3. The stationary situation created by the present trench warfare which has lasted for so many months.

The allies were unfortunate in having the most complicated situation to cope with at a time when the sanitary organizations were least able to meet it. I cannot report personally how the wounded were transported at that time. There is no doubt that a large number fell into the hands of the Germans.

Our actual experience began with the German retreat in the battle of the Marne—the advance of the Allies. At that time the problem which confronted the Sanitary Service was twofold: The hospitals of the North had to be evacuated, and in addition, some 112,000 men who fell during this memorable battle had to be transported to the various hospitals. This, too, came at a time when the *Service de Santé* was still badly prepared for its work. Ours were the only ambulances which were ready at that time. Our souls were harrowed by tales and sights never to be forgotten—hundreds abandoned without food and drink for days in half ruined churches or schools, or again lying on straw in slanted cars which could not be sent forward on account of the railway being used by ammunition and troop trains. The mere mention of the battle of the Marne evokes souvenirs of the many expeditions we made to Meaux, Lizy-sur-Ourcq, Crépy-en-Valois, etc., and it is hard to refrain from recalling here some of our experiences.

It was during this period that we gained much

of our experience in transporting the wounded from the advanced lines. We were kept very busy, our motor ambulances being the only ones which were in readiness to respond day and night to the calls of the sanitary authorities.

Before describing the various means of transportation I wish to say a few words about the obligations which we owe to the wounded. When we see the wounded arriving at our door we are too apt to look upon them as subjects to whom we intend to give the best of care, but for whom we do not have the keen, deep human sympathy which we should feel, did we but realize the physical and mental suffering through which they have just passed. It is well for us to remember the agonizing hours spent on the battlefield, and the complicated and nerve-racking journey which has finally landed them at our doors.

Dr. du Bouchet spoke very feelingly at our last meeting of our duty to the men who have fought bravely for their country. Our duty should begin not only with the treatment given them to alleviate their physical suffering, but the very minute we meet them. These men have left their homes, their occupations, their wives and their children to lay down their lives if need be for their country. They have fulfilled their duty to society, and our obligation to them, the humblest of them, is to treat them with the greatest gentleness and patience.

In order to evoke in your minds a complete picture of that journey (which so often, alas! ends in a tragedy) which the wounded soldier takes from the firing line to our hospital, let us start on the battlefield itself. For a description of what generally happens on the firing line I am indebted to our military colleague, Dr. Perrin, who was wounded near Arras, in the accomplishment of his duty, and who, fortunately, has almost regained his health in the American Ambulance.

I think there is great interest in following the wounded soldier from the battlefield until he reaches the point where our base hospital comes in contact with him. If he is wounded in the open, he falls on the firing line, and tries to drag himself to some place of safety. Sometimes the fire of the enemy is so severe that he cannot move a step. Sometimes, he seeks refuge behind a haystack or in some hollow or behind some knoll. Generally a number of wounded will collect in the same place. This is called by the picturesque name of *nid de blessés* or "nest of wounded." If the artillery or rifle fire is particularly severe, they will remain here till darkness comes on. In the meantime they apply a dressing to their wounds or have them dressed by some comrade. Under the cover of darkness, those who can do so, walk with or without help, to the *Poste de Secours* or First Dressing Station which, in open warfare, is situated from 500 to 1000 metres from the firing line, generally in some protected spot. As we shall see later on,

in trench fighting the *nid de blessés* becomes the *Poste de Pansement* in a third line trench.

Of course there are various ways in which the wounded can get to the *Poste de Secours*. Stretcher-bearers are sent out to collect the severely wounded. Sometimes mules are used, with an arrangement of side-seats called a *cacolet*, or a two-wheeled push cart, similar to the Japanese *pousse-pousse*. This vehicle is of the greatest service when the roads are good, and Dr. Perrin recounts that he succeeded one night in transporting 18 badly wounded soldiers from a spot 50 metres from the German lines to a point several kilometres back, in a very short space of time.

The wounded are not kept very long at the *Poste de Secours*. Their wounds are dressed, and in the case of fractures, improvised splints are applied, and the patients are evacuated as speedily as possible. This is accomplished by a system of ambulances, which operate from another service called the *Service de l'arrière*, but the number of motor ambulances is wholly inadequate, and this is a serious flaw. I am told that frequently the ambulances do not make connections, and that the surgeon of the battalion in charge of the *Poste de Secours* must get his wounded out as best he can, requisitioning for this purpose the peasants' carts and wagons. The dressing station does not part with its stretchers, so the wounded are placed on straw spread on the bottom of these carts without springs, and thus they are conveyed during five or six hours before they reach the sanitary train or temporary field hospital. What torture many of them must endure, especially those with multiple fractures!

This description applies to open warfare such as existed in the early stages of this war. The sanitary service, as well as the combatants, has been obliged to adapt itself to these new and strange conditions, and I am quoting from Ferraton, who describes the practical workings of the service under his direction.

The hardships of the soldier in this trench fighting have been shared by the military surgeon and his associates, and one must express the highest admiration for their coolness and courage under most trying conditions. Here, there is no Geneva convention. The medical corps is exposed to the enemy's fire in exactly the same degree as the soldiers. The military surgeon, as well as the stretcher-bearer, remains behind the combatants, in third line trenches, in trench-rooms, covered with transverse logs and sod. As soon as a soldier is wounded, the stretcher-bearers go to get him by means of the communicating *couloir* or trench. The ordinary stretcher is too long to be used in the tortuous and abrupt angles of these trenches. It has been found more convenient to use a sort of a palanquin made by suspending a canvas sling from a wooden pole. An ordinary chair is often the most convenient means for transporting the

wounded from the first trench to the so-called *Poste de Pansement* (dressing station). This *Poste de Pansement* is often situated in a second line trench.

In this subterranean room, dimly lighted, the dressings are applied, splints adjusted, hemorrhages arrested by means of an Esmarch bandage, and warm drinks given. There is generally at least one of these *Postes de Pansement* to each battalion. As soon as the shelling permits, the wounded must be carried to the *Poste de Secours*, which is generally situated a hundred yards or so in the rear, in some house. The wounded are carried to the heads of the communicating trenches, and at a favorable moment, transported on litters, either with or without wheels. At the *Poste de Secours* some immediately urgent operations may be performed, such as ligating for hemorrhage, tracheotomy for threatened asphyxia, etc. At this point ends the regimental service, and the divisionary surgeon takes charge. He has disposal of various horse-drawn ambulances or two-wheeled push carts.

In one particular division described by Ferraton (*Société de Chirurgie* of 16 March) the *Poste de Secours* was in a subterranean chamber hidden under a hay stack, and another was situated in the cellar of an abandoned house; in each case relatively safe from the shells which were bursting all around.

From the *Poste de Secours* the wounded are carried to the so-called Ambulances, of which there are two kinds:—

1. The first line divisional ambulances.
2. The ambulances of the second line (*Ambulance de Corps d'Armée ou de deuxième ligne*).

The first line ambulances, which, during the prolonged trench warfare have remained stationary, are generally, under ordinary circumstances, very mobile. The whole service can be packed on a few horse-drawn carts. They possess no beds, and are generally established in abandoned houses, the wounded being placed on clean straw. The duty of these ambulances is to receive the wounded sent by the regiments, perform the most urgent operations, but, more particularly, to make a choice of the wounded for distribution, hence the name *Ambulance de Tri*.

1. The slightly wounded are kept near the front.
2. The moderately wounded, who can stand a long journey, are sent to a sanitary train.
3. The very seriously wounded, who can only be transported a short distance, are sent to some neighboring ambulance.

The first group will be transported to a *dépôt d'éclopés*, the second to the evacuation hospital of the army corps, and the very severely wounded to a neighboring fixed surgical ambulance.

This latter is what is called a second line ambulance. It is situated in some neighboring village where there are comfortable buildings, and

where a good surgeon can perform many urgent operations on abdominal and head cases.

These hospitals may have a capacity of 50 to 100 beds and would quickly become overcrowded if the patients were not being constantly evacuated, either by means of a sanitary train to a base hospital, or, if too weak, to some surgical hospital of a neighboring village. The wounded have, therefore, successively passed by the Dressing Station (*Poste de Pansement*), the *Poste de Secours*, and the Distributing Ambulance (*Ambulance de Tri*). In this latter place they may remain not over 15 hours, often only a few hours, and from here, according to the gravity of their wounds, they are transported by horse-drawn vehicles or motor-ambulances to the *dépôt d'éclipsés*, the evacuation hospital, or the ambulance hospital. If the service is well done, the wounded are delivered at the ambulance hospital from four to eight hours after having been picked up, and, in many cases, within two to three hours.

At the immobilized ambulance hospitals, the badly wounded cases are supposed to be kept, i.e. the head, chest and abdominal cases. The others are forwarded to the sanitary trains or canal boats or sanitary ships to be distributed according to the gravity of their lesions to more or less distant hospitals. The head station of these sanitary trains is called the *Gare d'Origine d'Etapes*, and the station of arrival is called the *Gare de Répartition*. There are two such depots in Paris, the Gare d'Aubervilliers and the Gare de la Chapelle St. Denis, with which our ambulance drivers are very familiar. This latter station, where sometimes 2000 wounded arrive in a day, is in charge of Dr. Quénu and is admirably organized.

This is where I shall try to prove that the methods of transportation could be greatly simplified by a better use of motor ambulances. You see how complicated the machinery is for transporting the wounded from the firing line, and how important it is that every stage of that complex journey should be carefully planned and carried out. By the judicious use of motor ambulances much of the changing from one vehicle to another would be obviated.

I must here give a short description of various

forms of motor ambulances, and I must be forgiven if I speak a little more in detail of our Ford ambulances which have stood the test of nearly six months' steady use, both in field and base work.

In the early part of the war, whilst the committee was organizing this section of our American Hospital, I remember one day, on coming from a committee meeting, at the offices of the American Radiator Company, in Bd. Haussmann, seeing one of these cars standing in front of the door, the chassis being furnished with crude ambulance bodies made from wood of packing cases. It was a surprise to us. We knew they were being built, but we did not expect they would be ready so soon. I remember my emotion when Dr. du Bouchet and another member of the committee rode round the block, whilst we anxiously awaited their return and their opinion. The car was pronounced most comfortable, and it has since justified that verdict.

That was the first appearance of the Ford ambulance, and while some modifications have been made as to the details, the principle remains the same. The advantage of this car for work at the front is at once apparent. Its lightness, its exceptional clearance from the ground, and the power of its engine make the car a perfect one for work immediately behind the firing line. In the North, when the roads were muddy and bad, it was the only car which could get off the road into the mud to allow a convoy to pass and yet get back upon the road without the aid of a tow-rope. In the East, in the Vosges mountains, where one of our sections is working in Alsace, they take the hills so well that the French soldiers have nicknamed them "the goats."

Though we have not modified the general shape of the ambulance, we have gradually improved the model, with regard to the comfort of the patient and also of the drivers. We found that a third stretcher would be of help, and this has been supplied. This emergency stretcher is placed on a wooden frame, which can be either strapped out of the way against the roof of the car, or secured in the center of the car above the other two stretchers.

Three lying-down cases are all that a Ford car can safely carry over rough roads without straining the springs. As for sitting cases, four can be accommodated in each car. At first we

allowed the wounded to sit on the floor with their backs against the sides of the car. Then we thought seats would be better, and we now have two transverse seats for four sitters.

So far as the Ford is concerned, I feel that it has a great future as an ambulance. In the transportation of the wounded the patients are most comfortable. At present, the wounded are being transported over 60 kilometers over rough roads to our branch hospital, at Juilly, and the men all declare that they much prefer to ride those forty miles to the journey of eight or ten miles which they had to make from the front to the first clearing hospital in such vehicles as I have just described—springless carts, etc. In fact, many of the men fall asleep in our ambulances during the journey to our hospital.

The larger cars of the Daimler or Wolsley types, carrying four lying to six or eight sitting, are good for base work, but they are too cumbersome to be able to run very close to the front. On the other hand, the Ford, with its low outline, can creep very close to the firing line without attracting the fire of the enemy.

To resume, motor-ambulances may be made to carry two, four or six lying cases, or from four to eight sitters. The stretchers may be pushed into the car from behind or from the sides, as in the Austrian model, and in a new ambulance invented by Com. Denain, of Versailles, which is now being made for the French Army, of which I am showing you an illustration.

This new ambulance is very ingenious and very practical. It loads from the side. The

whole frame supporting the four stretchers rests on two transverse buggy springs, which absorb the shocks and make riding over rough roads

very easy, obviating longitudinal or transverse vibrations. All these points may seem trivial, but they are of the utmost importance so far as the comfort of the patient is concerned.

Many systems of suspension of stretchers based on spiral springs do not take this into account. I have several times tested this form of suspension by riding around over rough roads—and have found the vibrations most disagreeable, and realized how agonizing such a trip would be to those suffering from fractures.

The same criticism applies to the three-stage apparatus installed in so many of the sanitary trains. I refer to the Brechot-Deprez-Ameline

suspensions in which the stretchers are also supported by spiral springs.

The conclusions are obvious: the greatest comfort of the patient is obtained when the stretcher

is placed directly on the floor of the ambulance (as in the Ford), on rails (as in the Daimlers), or on rigid arms (as in the Denain). If placed on springs these must not allow of a transverse or longitudinal movement, but only of a vertical one.

In the transportation of the wounded the comfort of the patient should always be the first thought. The most painful injuries are compound fractures of the femur, and transportation is almost impossible unless the limb has been immobilized in some way. In our experience, the following simple appliance which Dr. du Bouchet taught us to use, was found invaluable. It consists of a double pillow filled with excelsior, which is placed round the limb and held in place by means of wooden splints, the whole secured together by means of straps and buckles.

I was impressed with a metal extension splint which Dr. Blake demonstrated to us at our last meeting. I believe this would bring even greater comfort to the wounded than our splint pillows.

The necessity of keeping the wounded warm during transportation is of paramount importance. It must be remembered that these poor men are generally suffering from traumatic shock, and that they easily get chilled. Even though they are covered with blankets, they lie on the cold canvas of the stretcher, with no blanket under them. We, therefore, tried to find a method of heating the car, and to keep the cold air out we secured the canvas sides and back. One of our members tried to utilize the heat of the exhaust pipes to warm the inside of the car. Though our experiment was not a success through a mechanical error, I am quite sure that the idea is a good one and could be worked out if the season were not too advanced for heating to be necessary.

In most cases sufficient heat can be obtained from a hurricane lamp which is kept lighted, suspended from the ceiling.

Now let me say a few words about sanitary trains, of which, as you know, there are three kinds: the *improvised*, the *permanent*, and the *ordinary passenger* train used for the sick or slightly wounded.

Unfortunately, our experience during the battle of the Marne taught us that there was a fourth train used for the transportation of the

wounded, though it could hardly be called sanitary. This was composed of cattle cars which had been used for conveying horses to the front.

Of course the military operations were such that there was no time for any attempt to establish a sanitary train. Straw was spread on the floors of the cars and the wounded placed on it. It was at that time that so many of the wounded contracted tetanus and developed gas gangrene. Many lives would have been saved if

a little time had been taken to clean and disinfect the floors of these cars before placing the wounded upon them.

The most common train is that composed of baggage or cattle cars with the Brechet Ameline apparatus in either end, consisting of three tiers of three stretchers each, each car carrying eighteen wounded. In winter a little stove is placed in the middle.

The best train that I have seen is composed of second or third class compartments, with lateral doors, which permit the stretchers to be easily carried in and out (but it must be recalled that portières vary in width of opening, many of them being too narrow to permit of the passage of a stretcher).

The carrying capacity of these trains is 250 to 350 wounded, about four-fifths of which are sitting cases; in other words, there are but 60 to 70 lying cases in each train. There are about 20

orderlies, and one surgeon (rarely an assistant surgeon) to each train.

Unless the cars are intercommunicating, the surgeons can inspect his cases only at the stations, and these are sometimes three to six hours apart. This means that the wounded are practically without medical supervision during the whole duration of the trip, and when the train reaches the "*Gare d'évacuation*" or Distributing Station the methods of determining the gravity of the wounds are wholly inadequate. Fortunately, this service has been greatly improved.

Another defect in the system is the method of feeding the wounded. Often there is no provision for feeding them on the trains, and this is carried out at the stations where the infirmaries are established. Here the soldiers are stuffed with unsuitable eatables often, which causes indigestion and other troubles for those who are unable to take solid food.

The already lengthy journey is made almost interminable by frequent stops. The speed of the train is almost 40 kilometers an hour, and the trip from Amiens to Bordeaux, for instance, would take 48 hours. If the feeding of the patients was attended to on the train, the duration of the trip could be reduced one half. This has been tried recently on some of the trains with success, a restaurant car being attached for the feeding of the wounded and the personnel.

I want to speak of a little experience which I had (but fortunately this condition has been corrected now). I have seen a surgeon going from car to car, simply asking the orderlies if any of the men complained. If none complained (and do we ever hear these brave soldiers complain?) they were allowed to remain where they were and sent on to some more or less distant hospital in the provinces, many deaths resulting from the delay.

Another means of transportation is the canal boat or *Péniche Sanitaire*. I have had no experience with this method of transportation, but it seems to me that its great objection is that it is very slow and keeps the wounded from reaching a well-equipped hospital quickly.

I saw some magnificent sanitary ships at Boulogne, used to transport the British soldiers to England. This is undoubtedly one of the best means of evacuating the wounded, particularly when the sea is calm.

To resume: The conditions to be met in the transportation of the wounded are *comfort, speed and safety*. The first two we have dealt with, and the question of safety I will now consider. Safety implies not only the proper treatment of their wounds, but also the proper precautions against danger of contagion from the medical cases.

In the beginning of the war there were practically no medical cases, but as the war goes on, the medical cases, among which is a large proportion of contagious diseases, are increasing in number. At least one-half of every sanitary

train is composed of medical cases. They try to separate the contagious cases in the train, but it is very difficult to carry out this isolation when the surgical and the medical cases are not kept entirely apart. This defect in the transportation system is a very serious one.

To distinguish the cases readily, the soldiers should be carefully tagged with ears of different colors; for instance, *red* for surgical, *blue* for medical and *yellow* for contagious cases.

Having described, very imperfectly, the various methods of transportation now in use, I want to say a few last words on what I consider would be the ideal method of evacuating the wounded from the front. I should like to see the trains used only for the lightly wounded and medical cases, while the severely wounded should be conveyed by motor ambulances directly from the firing line to the temporary or even to the base hospitals.

This plan should be realized by the use of motor ambulance convoys attached to each army, and assuring a regular service between the first dressing stations or first clearing hospitals, and a base hospital. This would do away with the various and painful changes, the exhausting waits and the inevitable delays. I am sure that this would mean the saving of many lives.

I have already been too long, and there is no time to describe our own ambulance organization. Suffice it to say that it is fitted for just such work. Our units of 20 ambulances with a staff car and a repair car could be multiplied *ad infinitum*, and would be admirably suited for this convoy work.

It is with legitimate pride which should be shared by all Americans, that I am able to report that our various ambulances driven by volunteer Americans, have carried to date over 26,000 wounded soldiers, French, British, Indian, Belgian and German. Our American ambulances are now familiar objects all along the line. It is quite a common occurrence for our men to evacuate wounded from a sanitary train in Paris who have already been carried from the first dressing stations at the front to the head station of the sanitary train fully 200 miles from Paris.

FIRST IMPRESSIONS OF THE OPPORTUNITY FOR ORTHOPAEDIC WORK AT THE AMERICAN AMBULANCE.*

BY ROBERT B. OSGOOD, M.D., BOSTON.

I HAVE been somewhat uncertain since coming to the Ambulance as to just what an orthopaedic surgeon is supposed to be or to do. In a "*sauf-conduit*" I have been described as an "*orthopédiste*," which is apparently a chiropodist or corsetier.

* Read on May 7, 1915, at one of a series of medical meetings held at the American Ambulance, Neuilly, Paris.

In France, orthopaedic surgery has been most closely associated with tuberculosis of the bones and joints in children, and you are all familiar with the splendid work of Dr. Ménard and Dr. Calvé at Bercy-sur-Mer. This type of orthopaedic work was the type from which the name of the specialty originated: *orthos*, the Greek word meaning straight, and *pais*, a child, i.e. straightening crooked children. Of late years, especially in America, we have been receiving some crumbs from the masters' tables of Medicine and Surgery among adults and like to derive the words from *orthos* and the verb *paideuo*, meaning to educate or to train straight, quite without regard as to whether children or adults are concerned. At any rate, let us not conceive the word to have anything to do with the Latin word *pes*, meaning foot, although this impression is very common because foot strain, especially in America, is so frequent a cause for orthopaedic treatment.

At first thought there would seem to be very little opportunity for orthopaedic work at a war hospital. Our friends among the enemy, however, are evidently finding this is not the case, and Professor Lange, the preëminent German orthopaedic surgeon, has been busy, both at the front and in Munich, which I believe has been made the orthopaedic base. I have here two interesting monographs by him on orthopaedic work in war which have lately been published. In England also Mr. Robert Jones has been put in charge of orthopaedic work of the English forces, and Liverpool has been made the orthopaedic base.

One can only give impressions, and I hesitate to mention even these after a few weeks' experience, being quite aware of the pity, if not the contempt, with which we treat the stranger who spends a week in America and then describes the race. It has been of great interest to see the very large number of compound and comminuted fractures, almost all of which are septic when they enter the hospital, and need further drainage. These present special problems which are unusual. The necessity for frequent and copious dressings and often constant drainage goes hand in hand with the necessity for immobilization as complete as may be, both for the promotion of union in good position, and the prevention of osteomyelitis of a chronic type.

It is only an impression, but a fairly definite one, that in these necessarily long-continued cases a problem quite as important as the healing of the original lesion is the conservation of motion and function in the joints in the neighborhood of the lesion, even if they have not been themselves originally injured. Stiff shoulders, elbows, wrists, knees and ankles are crippling in themselves, and once a fibrous ankylosis is firm, its healing is likely to require a far longer time than the healing of the original injury. If this stiffening can be prevented without sacrifice of the efficiency of the treatment directed toward

healing the original lesion, it is surely quite worth while thus to prevent it. To make the point clear, a fractured humerus treated without abduction of the arm will frequently be followed by an adherent sub-acromial bursa or a stiffness of the shoulder joint proper. If the arm is constantly and deliberately abducted once or twice daily, or the fracture can be treated in constant abduction, no stiffness need result, and in the case of a joint lesion, the arm will be in the best position for use in case permanent ankylosis of the joint occurs. There is perhaps no joint in which the position in which it is placed is of so much importance to its future function as the elbow, and ankylosis or restricted motion is very common. An angle a little more obtuse than a right angle means the patient cannot touch his face or feed himself; an angle a little more acute than a right angle means very satisfactory function. The hip has so wide a range of motion and is such a firm joint that, provided adduction and flexion are prevented, the eventual function is good. The knee position depends entirely upon the probable end result as to stiffness or motion. If complete ankylosis is to be expected a slight degree of flexion is more comfortable and useful. If any eventual motion is likely, hyperextension is most to be desired, since walking on a partly flexed joint in which there is motion is likely to become increasingly painful and to lead to many chronic articular changes. The ankle should always be flexed at a right angle. Perhaps this is not quite as important to the French women as to the French men since the national heel insists upon a certain amount of equinus.

Two important groups of cases have been apparently quite common at the Ambulance, resulting from nerve lesions and consisting of localized paralysis. The first is wrist drop from injury to the musculospiral nerve, and the second is foot drop due either to a spinal cord injury or to a lesion of the external popliteal nerve. Mr. Robert Jones has always emphasized in cases of paralysis, more particularly paralysis of poliomyelitis, the importance of preventing overstretching of the paralyzed muscles by allowing the malposition to be maintained, so that we may consider that apparatus may be not only retentive, but corrective as well. It is very pleasantly surprising frequently to see seemingly paralyzed muscles regain power when they are taken off the stretch as by a "cock-up" or elastic traction splint for the wrist or a toe drop splint for the foot.

We have had one case which illustrates the value of immobilization in cases of toxemic arthritis when the process is acute. These cases will undoubtedly be rare in a war hospital, but may very well occasionally occur secondary to a septic process. Immobilization in these cases of the affected joints, not only gives relief to the pain, but seems definitely to make less likely the spread to other joints and to diminish the con-

stitutional effects which are frequently very much more marked in joint infections than when other and quite as important tissues are involved.

There can hardly be any question as to the value of the appreciation of the principles of the prevention of deformity to the cases under treatment, and the importance of it as an economical measure for the hospital and for the Government is obvious. Later on, undoubtedly, surgeons will have the opportunity of acquiring a more perfect technic in operations for recovering motion in stiffened joints. Arthroplasty is still in its experimental stage, despite certain brilliant results and much literature on the subject. One essential has been already emphasized; this is that a long time, perhaps a year, should elapse between the subsidence of a septic process in a joint, and the attempt to obtain motion by an arthroplastic operation. The field, however, must evidently be enormously widened by the unfortunate lesions of this war.

It may be of some interest to you to see some of the apparatus which is being employed by the Harvard Unit; little of it is original, and it is of value only in so far as it makes war surgery more easy and aids in preventing and correcting deformity and adding to the comfort of the patients.

I wish especially to thank Miss Cassette, in charge of the supply and apparatus department, for her great help. The apparatus work in the Ambulance is already of such a high grade that I fear we have simply brought coals to Newcastle.

SOME PARALYTIC CONDITIONS RESULTING FROM SURGICAL AND OBSTETRICAL ACCIDENTS.*

By JAMES WARREN SEVER, M.D., BOSTON.

*Junior Assistant Surgeon, Children's Hospital, Boston;
Surgeon, House of the Good Samaritan.*

I have been asked to give you tonight a brief resumé of some of the more common paralyses following surgical and obstetrical accidents. None of these conditions are of common occurrence, fortunately, in any one man's experience in general practice, but are frequently seen in hospital clinics. This is especially true of two such conditions as cerebral spastic paralysis and obstetrical paralysis, which are seen in children in considerable frequency in various nerve departments of hospitals.

The other two conditions which I shall take up are Volkmann's ischemic paralysis and paralysis of the musculospiral nerve following fracture of the shaft of the humerus.

Volkmann's Ischemic Paralysis. In 1869 Volkmann first described the clinical picture of a contracted wrist and hand following a fracture, with atrophy of the forearm, known since as Volkmann's paralysis or contracture. His first case, however, occurred in an acute synovitis of the knee, following the application of a ham splint. The gastrocnemius muscle showed diminished electrical reaction and a moderate amount of contracture, which improved without operation. His first paper was followed by another in 1881 in which he emphasized and elaborated certain points.

Lesser, in 1884, reported seven cases of fracture of the arm involving either the humerus or the two lower arm bones, followed by Volkmann's ischemic paralysis. He also attempted to reproduce the condition experimentally in twenty-three rabbits, but was unsuccessful. Others since have tried to reproduce the condition by animal experimentation of various sorts, directed towards the muscles and arteries, but have failed to get conclusive results.

What are the Causes of Volkmann's Ischemic Paralysis? Volkmann has laid down the statement that the condition follows the use of too tight bandages, usually after fractures, particularly on the arm, and occasionally on the leg, and that the paralyses and contractures are ischemic in origin, due to the cutting off of the arterial blood supply. He states that the paralyses and contractures generally come on together, while paralyses due to nerve pressure come on gradually. There is always great rigidity of the muscles from the first, due to great swelling, so that the part has a woody feeling. The ischemia is not complete, in that the part does not become gangrenous. The condition may also be seen after ligation, rupture and contusion of the blood vessels, as seen in a case reported by Astley¹ of Philadelphia in 1908, due to an embolus or thrombus of the brachial artery.

Murphy² states that he believes the condition is due to a blood and serum effusion in the sub-fascial zone, which causes cyanosis of the whole arm from pressure, followed by inflammation of this blood clot. The pressure, caused by this effusion, results in muscle cell destruction and necrosis, aided by tight bandages and splints. He believes that tight bandages, aided by tight skin and fascia, cause the damage, which is practically all accomplished in the first forty-eight hours. In other words, it is a traumatic myositis, resulting in permanent destruction of muscle tissue and so contractures, with or without nerve involvement in the scar tissue so formed. He does not agree with Volkmann, that injury to the artery plays any part in the destruction of the protoplasm of the muscle cells,

* Read by invitation before The Brookline Medical Society, April 5, 1915.

but that pressure from the exudate and venous obstruction are the factors which cause the subsequent train of events.

Most frequently the condition is seen following fractures of the lower portion of the humerus and the bones of the upper forearm in children. The supracondylar region seems to be the region of election, and the majority of cases seen are under fifteen years of age.

The irreparable damage to the muscle is accomplished within the first three days, but the full extent of the contractures does not appear at once. The damage is always done on the flexor surface of the part and is a flexor contracture and never an extensor contracture.

There is almost always some impairment of sensation or paralysis of the small muscles of the hand, due to nerve involvement or injury at the time of the accident.

The pathological muscle changes represent typical hyaline degeneration and disappearance of muscular tissue in varying degrees, according to the severity of the original process.

Symptoms and Onset. Now what is the method of onset and what are the symptoms? After a fracture, usually of the upper extremity, which has been splinted and bandaged, there may be noted incipient swelling of the part, with stiffness and cyanosis of the hand and fingers and forearm. There is almost always marked and intense pain, more than can be properly due to the fracture *per se*. These conditions are soon followed, if the bandage and splint are not removed, by limitation of motion and then complete loss of motion in the hand and fingers. The swelling may subside of itself, if the splint and bandages are not removed, but greater damage will probably be produced, and pressure sores are likely to result. If, on removal of the bandage and splint, great swelling is present with a very tight skin, free incision into the forearm should be made in order to relieve the tension. Probably in some cases this procedure would be of great help and relief.

Following the Establishment of the Contracture, What Is to be Done? Many methods have been tried to relieve the contracture, but none has been wholly successful. As the arm grows, the muscles and tendons become relatively shorter and so lead to greater contractures. The bones of the forearm have been shortened in a number of cases with and without benefit. Tendon lengthening has been tried and again has proved to be of use in certain cases, but is a long and elaborate operation, and is quite likely to lead to more adhesions. The method which seems to offer the best result is the one which divides the muscle bellies by free incisions and so lengthens the tendons.

The after-treatment is of the greatest importance and consists of the use of a palmar and dorsal splint to prevent and reduce the contractures of the wrist and fingers; electricity, galvanic and faradic, if there be nerve involvement, and

massage and manipulation. Treatment should be long continued, but in many cases the benefit to be derived from any or all of these methods is not very great, and it is only rarely that a very useful hand is obtained. The results, however, are much better than if nothing had been attempted.

Musculo-Spiral Paralysis. This condition is not very rare, and usually follows fracture of the middle third of the shaft of the humerus. The musculo-spiral nerve, as it passes around the humerus from behind and to the inner side of the humerus, downward, outward, and forward in the musculo-spiral groove to the outside of the humerus, becomes involved in the callus or impinged on by a spicule of bone. Involvement of the nerve and subsequent paralysis may follow fractures of the upper third and lower third of the shaft of the humerus, but its occurrence under these conditions is very infrequent.

Its occurrence is a serious accident and complication, and usually calls for careful study and possibly surgical interference. It is a condition which may be overlooked at first, and is not usually noticed until the splints are removed and the patient attempts to move his hand, when it is noted that there is paralysis of the extensor group of the arm and hand, resulting in the typical wrist drop. The hand is held pronated and there is no power to supinate.

The paralysis is usually wholly motor, even when the nerve is greatly injured. There may be some slight impairment of sensation, but it is never very great. The reason of this preservation of the sensation, when the nerve is so greatly injured, may be attributed to the fact that the cutaneous branches leave the trunk of the nerve above the fracture and probably carry sensation to the radial half of the hand. Sensory symptoms have no relation to the amount of motor impairment; when loss of sensation is present, it may usually be found in the distribution of the radial nerve in the hand, namely, on the dorsum between the metacarpal bones of the thumb and forefinger.

Period of Onset. If the nerve is torn at the time of fracture, there is, of course, immediate loss of function, and paralysis at once appears. If due to involvement in the callus or pressure from bone spicules, the onset is more gradual and will probably not appear until about the beginning of the third week.

The prognosis is usually good if the condition is recognized early. About 50% of the cases require operation. Others get well without one. In cases where involvement in the callus is the only condition present, the result from operation will generally be perfect. In others, where the paralysis is due to tearing, stretching, or complete section of the nerve with separation of the ends, an early operation offers better results than a long deferred one, but even with nerve suture or nerve lengthening, the results

may not be ideal or even good. The following case is one of interest:—

Several years ago I saw in consultation at the Waltham Hospital, a man who had had his arm broken in two places. The fractures were located at about the junction of the middle and upper third of the humerus and at about the junction of the middle and lower third of the radius and ulna. I saw him about four months after the date of fracture, and after the union had become solid. One month after the fracture, it was noted that he had a wrist drop and paralysis of the extensors of the forearm with no voluntary motion of wrist or fingers. Subsequently, he had typhoid fever, from which he was convalescent when I saw him.

The injury was on October 2, 1909. The paralysis was noticed on November 2, 1909; and on February 28, 1910, I operated on him. X-rays of the humerus showed that there was moderate lateral displacement of the fragments of the humerus, with only a fair amount of callus. The operation showed that the musculo-spiral nerve was stretched tightly over the sharp lower edge of the upper fragment and then became involved in the callus. The nerve trunk was very thin and atrophic, but was continuous. It was freed thoroughly and lifted up, and under it, between it and the bone, was sewed a piece of the triceps muscle to prevent further callus involvement. Following this, the bones of the lower arm were resected as they were overriding. The ends were approximated and held together by kangaroo tendon. He made a good recovery and in three months had a useful arm, but still had some slight paralysis persisting. He was again operated on on May 27, 1910, and a few spicules of bone were removed from the inner aspect of the humerus at the site of the fracture through an incision on the internal aspect of the arm. These spicules pressed on the portion of the nerve as it began to wind about the humerus on its internal aspect. Following this he made a perfect recovery. In October of 1910, five months later, he was readmitted for a fracture of both bones of the same arm in another location, following a fall. At this time he had completely recovered from his musculo-spiral paralysis.

It is probable that if this case had not been operated on, sooner or later the edge of bone would have completely cut through the nerve and the chances of success then from operative procedure would have been much diminished.

Increasing paralysis demands surgical intervention in these cases, as well as a paralysis which shows no tendency towards improvement. After-treatment is always of the greatest importance and is to be carried out by means of massage, electrical stimulation, baking, and active motion as far as possible.

We will now take up paralysis accompanying obstetrical cases:—

OBSTETRICAL PARALYSIS, OR BIRTH Palsy.

Obstetrical paralysis, or birth palsy, is produced by injury to the fibres of the brachial plexus, usually the result of a difficult labor, and caused by forcible separation of the head and shoulder on the affected side. Obstruction to the after-coming head, with a pull exerted on the shoulder, or vice versa, is the accepted method for producing the nerve lesion. T. Turner

Thomas of Philadelphia states he believes that the paralysis usually results from a laceration of the axillary portion of the joint capsule, following an injury to the shoulder joint itself, occurring at birth. This tear in the capsule produces an inflammatory serous exudate which involves the branches of the brachial plexus adjacent. He believes that there is always in these cases a primary traumatic subluxation of the head of the humerus, accompanied by a laceration of the joint capsule, rather than a primary nerve lesion. He fails to back up his statements with pathological evidence, however, of which there is sufficient on the other side to tend to disprove his theory. It is perfectly true that later, as the child grows older, there is, in many cases, a posterior subluxation of the head of the humerus, accompanied by bony deformity of the clavicle and acromium. Early cases, in mine, and others of larger experience, have never shown this condition. Congenital dislocation of the shoulder is not accompanied by brachial paralysis. Separation or fracture of the humeral epiphysis may be accompanied by paralysis resembling that seen in cases of birth palsy, and I have seen one such lately in an eight weeks' old baby. X-rays will generally show fractures or epiphyseal separations or dislocation of the joint, which may be of sufficient severity to cause secondary brachial paralysis.

The condition is usually noticed at once following delivery, and presents the following typical picture. The arm hangs at the side, limp and helpless; the hand is pronated; the elbow extended; and the humerus in extreme inward rotation. There is present a distinct inability to raise or abduct the arm at the shoulder, due to the paralysis of the deltoid and supraspinatus. The arm cannot be rotated out because of the paralysis of the infraspinatus and the teres minor. The internal rotation is marked and constant, due to the unopposed contraction of the subscapularis, latissimus dorsi and the pectoralis major.

This position is due to injury of varying degrees of the fibres of the brachial plexus from stretching or tearing forces, as shown by Clark, Taylor, and Prout,³ in experimental work and by autopsy on cases. The fibres may be torn, or may be compressed by a surrounding hemorrhage about or within the sheath of the cord, or the stretching may be accompanied by only a serous exudate within the sheath.

There are two distinct types of paralysis resulting from this injury, the so-called upper and lower arm types. The upper arm type usually is the more common and is the result of injury to the two upper segments of the brachial plexus, formed by the fifth and sixth cervical segments. When the seventh, eighth and first dorsal segments are likewise involved, the paralysis is more complete, and the so-called lower arm type results.

The upper arm type results in a paralysis of

the deltoid, supra- and infraspinatus, brachialis anticus, biceps, supinator longus and brevis. The lower arm type results in more complete paralysis, involving practically all the shoulder and lower arm muscles, as well as those of the hand.

Sensation is, as a rule, not impaired, due to the probable integrity of some of the unimpaired collaterals.

The two muscles which are usually spared are the subscapularis and the pectoralis major, the latter causing adduction of the humerus, and the former holding it in marked inward rotation. The reason for this is that the subscapular nerve is usually given off from the posterior cord of the brachial plexus and receives filaments therefore from the fifth, sixth, seventh, and eighth cervical segments. It is because of this liberal supply largely from the seventh and eighth cervical segments, that it continues to functionate, even if some of its fibres are destroyed which come from the upper segments, which are the ones most frequently injured. The pectoralis major is also supplied by a nerve, known as the external anterior thoracic, which comes from the outer cord of the plexus, made up of the fifth and sixth cervical segments, but also receives collateral branches from the seventh and eighth.

The fact that the supra- and infraspinatus are practically always paralyzed, points toward a primary injury to the plexus, for the subscapular nerve which supplies them, comes off from the plexus too far above the shoulder joint to be involved in any exudate which might be present about it as a result of a tear in the capsule.

The Arm Being Found in the Condition above Described, What is to be Done? It must be determined whether or not a fracture, dislocation or epiphyseal separation is present. This can usually be determined by the customary methods of examination, supplemented by x-ray examination. Tenderness and swelling about the joint are of importance, and tenderness on pressure above the clavicle over the course of the brachial plexus should be determined. Tenderness and swelling in the axilla might also indicate an exudate about the lower portion of the plexus.

Inequality of the pupils should be noted, if present. If there is an inequality, it means that there has been, without question, an injury to the inner cord of the brachial plexus, high enough up to cause stimulation of the sympathetic branch of the cervical sympathetic plexus, which sends off a communicating branch from the fifth cervical segment of the cord. The paralysis of the muscles involved should be determined as carefully as possible. As one of the commandments of orthopedies, I believe that it is essential to prevent deformity and contracture in any case. Therefore, it would seem best, in any case, to elevate, outwardly rotate, and ab-

duct the arm and hold the hand supinated. This can be done easily, and the position maintained by means of plaster of Paris, or by a wire splint. This position should be maintained at all times, except when the arm is released for massage and exercises, which should be done daily and for a long period, say, at least, several years. The maintenance of this position prevents contractions of the subscapular, latissimus dorsi and pectoral muscles, and stretching of the paralyzed ones. The principle is no different from that which we use in the early treatment of cases of infantile paralysis to prevent deformity. One good argument on the other side should be considered, however. Persons with long experience and good success in the treatment of these cases, say that it is not wise to fix the arm of a young baby in such an apparatus as has been described, for the fact that the child will forget to use it, and so it will be more difficult to make it use it. The child will become obsessed with the fact that the arm cannot be used and progress will be delayed and the end-result will not be so good. They believe that such contractures and malpositions as may occur or persist, are to be discounted in favor of early and constant use and training, rather than the possibility of no contractures and less ability to use the arm freely. Personally, I have not become convinced of the logic of this last argument, and still think that an arm in as good an anatomical condition as it may be possible to make it, will eventually be a more useful arm than one which has been allowed to become fixed in inward rotation through contraction, together with more or less posterior subluxation of the shoulder joint, as is almost always seen in the older cases. Corrections of these two deformities, together with osteotomy of the acromion, which frequently grows down in front of the head of the subluxated humerus in older cases and prevents its full replacement, generally results in a much better and more useful arm. Why not prevent the necessity for these procedures by taking the proper precautions at the beginning?

Probably subluxation posteriorly usually occurs, because of the excessive pull of the contracted subscapular and latissimus dorsi muscles, which pull the upper end of the humeral shaft backward, helped to a certain extent by the forcible adduction and inward rotation forces applied by the contracted pectoralis major.

Patience and perseverance are needed in the treatment of these cases, besides careful supervision over a period of years—accompanied by constant exercises and massage. The results in the past have been fairly good. The future promises better ones, in view of increased knowledge, or better, our different point of view and clearer understanding of the problem.

HOMOGENIZED MILK: ITS POSSIBLE APPLICATIONS TO INFANT FEEDING.*

By MAYNARD LADD, M.D., BOSTON.

Instructor in Pediatrics at Harvard University.

HOMOGENIZATION of liquids of different densities consists in reducing the constituent elements into such a physical condition that they will no longer separate, but will maintain a permanent and even composition throughout the mixture.

Briefly stated, this result is brought about by a powerful pump which forces the mixture through a finely ground agate valve against great pressure. After its passage, the mixture is perfectly homogeneous, and in the case of milk, or mixtures of milk and oils, the fat globules are crushed, torn and pulverized and so incorporated with the other elements of the milk, that they can no longer rise by action of gravity, separate after long standing nor agglutinate.

The mechanical device by which this result is made possible is the invention of M. A. Gaulin of Paris. His first machine was brought out in 1899. With this the fluid elements were forced through very fine capillary tubes, but the practical results were not perfect, owing to the fact that many of the fat globules passed through the smallest possible capillary tubes without alteration. M. Lindet, of l'Institut Agronomique, who had interested himself in Mr. Gaulin's invention, demonstrated that the ascending force of fat globules were proportionate to the cube of their radii, and that the principle of stabilization of milk consisted in reducing these radii to a dimension as near as possible to zero. The diameter of butter fat globules varies from 1/100 to 1/1000 of a millimeter, whereas the smallest holes that can be bored in a metallic surface is about 1/10 of a millimeter. This led M. Gaulin to adopt an entirely new method of carrying out his original idea, and in 1902, he announced his invention of a device which subjected the fat globules to great pressure between two surfaces, exactly adjusted to each other, but sufficiently elastic to permit the passage of the most minutely divided particles.

The essential patent in this homogenizing machine is an agate valve, so finely ground that it will leak only under great pressure, and held in its bed by a variable tension spring, which is regulated by a fly wheel with a screw end. The mixture is pumped against a pressure which may vary up to 500 kilos. The pumps vary in capacity from 50 to 2000 litres per hour; according to the size.

It is not my intention to enumerate in detail the commercial applications of this process, which has been extensively used on the continent and in England and to a considerable extent in this country. The chemical composition of the milk is in no wise affected, but in cases of milk

and cream mixtures, the physical condition is so changed that the fat can no longer be separated by the usual cream separators. In making the Babcock fat test more acids must be used and centrifugal action continued for a longer time.

Homogenization improves decidedly the taste of the milk or cream, particularly that of pasteurized milk. As the process prevents the separation of the fat, homogenized creams can be readily pasteurized. When commercial milk is to be transported long distances in warm weather, and its temperature allowed to rise from lack of proper refrigeration, the continual jolting to which it is subjected causes the cream to be churned into butter fat, and it is impossible to reincorporate it into the milk in its original form. The same disturbance of emulsion may, under similar conditions, happen to milk modifications. We are all familiar with the greasy surface seen in summer in the bottle of milk brought to the clinic by the mother who lives at a distance, so that a considerable quantity of fat is often taken into the baby's stomach in large indigestible globules.

The application of homogenization to ordinary whole milk or to any kind of a milk modification, will overcome this defect; and theoretically it would seem as if it would yield a much more digestible mixture. This is one of the points I hope we shall be able to determine in the series of cases I have planned.

Variot, in Paris, has used an homogenized milk in the "Goutte de lait" de Belleville. He claims it is taken as successfully as breast milk and has never seen cases of infantile scorbutus nor rickets which could be attributed to its use. Chevalier demonstrated by chemical analyses that the constituents of homogenized milk are more completely absorbed than those of simple sterilized milk. The more finely divided the food, the greater is its accessibility to the digestive fluids, and the greater its assimilation.

It is interesting to note also that when rennin is added to homogenized milk, the curd which results is a homogeneous flaky paste, resembling bling closely the curd of human milk.

The process of homogenization has a beneficial effect upon its keeping qualities. An official in the laboratory of M. Gaulin is authority for the statement that milk sterilized and homogenized has been shipped by various methods of transportation for more than 14 1/2 months, and at the end of that time has been found "as good as fresh milk," without the application of ice or addition of preservatives. This fact, if verified, might have an important and practical effect in the shipment of modified milk to distant points. It may be found that one or two shipments a week is safe and practical. If this is so, it would mean a great saving in expense to the consumer, and would facilitate the distribution of prepared mixtures to distant points.

Recently, while discussing various feeding problems with Mr. F. C. Howe of the Walker-Gordon Company, I first learned of this inven-

* Read before the meeting of the New England Pediatric Society on Feb. 26, 1915.

tion of M. Gaulin. The idea of utilizing it to improve the quality of ordinary milk modifications occurred to us at that time, and it required very little imagination to foresee a possible field for investigation into infant foods which may open many new lines of study. Through the kindness of Mr. Walker, and the coöperation of Mr. Howe, we were able to secure temporarily for experimental purposes one of the homogenizing machines and install it in the laboratory, where it could be run by the power plant of the refrigerating apparatus.

The most interesting application of this principle of homogenization is in connection with the fat constituent of milk modifications, especially in cases of so-called "fat intolerance." These feeding cases are, perhaps, the most difficult ones with which the pediatricist has to deal. Their general characteristics have been so well and so recently described before this society by Dr. Dunn, that it is hardly necessary to discuss them in detail tonight. Briefly stated, one recognizes a class of feeding cases in which the fat of cow's milk, if given in too large percentages, leads to a digestive crisis of a serious nature. The restoration of the infant's tolerance for fat then becomes a very slow and gradual process. During this period the nutrition suffers severely. There are, of course, all degrees of intolerance. The milder cases may generally be corrected and controlled by careful feeding. The severe cases often resist our best efforts and pursue an interrupted downward course. Certain of these babies are capable of digesting high percentages of carbohydrates and proteins so that the nutrition of the body can be maintained, but others are unfavorably affected by such an unbalanced ration. Without recourse to breast milk, they cannot be made to thrive.

The fact that the great majority of cases of fat intolerance occur in artificially fed infants, and the further observation that, in the first year at least, they generally respond favorably to breast-milk, raises the interesting question as to whether it is fat *per se* which causes the familiar symptom-complex or simply the peculiar qualities or reaction to the fat of cow's milk. Generally speaking, breast milk contains a much higher percentage of fat than that which has been given in the milk formula, and yet, under its use, the symptoms gradually disappear, and metabolism is restored to its normal basis.

These considerations have led to more or less experimentation with vegetable oil, and fats of other animals, such as lard, and with cod liver oil. But we have now an opportunity to combine such fats and oils with other milk ingredients in a practically perfect and permanent emulsion, so that we may reasonably expect a totally different result from their use.

If, as a matter of experiment, one can show that olive oil, for instance, is readily digested and assimilated when homogenized with skim-milk, in these cases of intolerance to cow's milk

fat, one can then seek by more detailed experiments, of a more exact and scientific method, to find out what element or elements of cow's milk fat is the source of the toxic substances which seem to be formed in the processes of digestion.

One of the most striking facts which recent metabolism experiments in infants has shown is the interrelation of the various ingredients of milk in normal metabolism. A disturbance in the digestion of an element frequently influences the metabolism of the other elements, and the end result, which we see in the vomiting, diarrhea, abnormal stools, malnutrition and toxemia, represent a very complex series of antecedent causes.

Now, if we can separate in a pure state and recombine into a homogeneous mixture the necessary food elements for an infant, we have advanced to an interesting stage of experimentation to determine some of the possible primary causes which start up the train of symptoms leading to the digestive explosions so often seen in the artificially fed infants.

It is possible, for instance, by this process of homogenization to combine an almost pure olein, or palmitin, or stearin with fat-free skim milk, and so eliminate almost entirely the influence of the various fats of cow's milk. By using a chemically pure precipitated casein, we can combine pure casein with pure oils and pure sugars of different varieties, adding artificially prepared mineral matter in varying proportions. Such mixtures, homogenized, may be found to be of use in exact metabolism experiments, although they would be too expensive and complicated for practical feeding.

We may combine a vegetable fat, such as olive oil, with precipitated casein, or fat-free lactic acid milk, and test its food value in acute diarrheas, or in convalescents from acute diarrheas, conditions in which the ordinary fats of milk are not well tolerated. I have had an opportunity so far to test the tolerance to olive oil in these acute infections in three cases only; one a convalescent from a severe infectious diarrhea, and two during an infectious diarrhea at the end of the first week of fever. In the convalescent case, the child, two and a half years of age, took two per cent. of olive oil in a fat-free lactic acid mixture and gained over a pound in four days. The case returned then to the country and I was not able to observe further its use.

In the other two cases the 1.50% of olive oil was given in a malt soup mixture. Both children, one one year, the other three years of age, have steadily improved. As the cases are far away from Boston and the parents have no means of weighing the children, my observation of the effect of the food is incomplete, but the result at least justifies the hope that such cases can be given food of higher caloric value by this method, with less disturbance of nutrition and greater conservation of strength. Dr. Wyman and I are planning more extensive and accurate

investigations along this line, through the courtesy of Dr. Bowditch, when the material which the Floating Hospital will furnish is available.

Mr. Howe is at present experimenting with the effect of an homogenized mixture, cotton seed oil and skim milk, upon calves. A perfect emulsion is obtainable. Whether such a food, which could obviously be produced at the minimum of cost, could be of use to infants, is at present interesting as a speculation only, but is worth investigation.

A more practical problem at once suggests itself in mixtures of olive oil and skim milk—especially in combination with the malt soup mixtures.

The type of food which I have found most useful in cases of fat indigestion with extreme malnutrition, is the malt soup mixture. Many of the worst cases are amenable to successful feeding by this method intelligently applied. However, we do meet with failures, and if we are to fairly test the applicability of an homogenized olive oil malt soup combination, we ought to select our cases from those who have been carefully fed in the past and yet failed to respond.

I have chosen olive oil for my first experiments, as olein is the principal fat of breast milk. The economic aspect of such a mixture, it seems to me, is of immense importance. The principal cost in milk modification depends upon the value of cow's fat or cream. Olive oil, even at ordinary retail prices, costs about one-fourth as much as cream. If combined with fat-free milk, the cost of a modified milk could be greatly reduced for the benefit of the poor, especially if we are able to demonstrate the possibility of keeping sweet and palatable, for several days a pasteurized homogenized milk.

Another point in connection with the malt soup olive oil mixtures is the effect of the homogenizing process upon the starch. The tendency for the barley decoction to separate on standing is strikingly prevented. In fact, any milk modification is improved in taste and appearance by this process of homogenization. It has been shown that whole milk so treated is more easily digested and assimilated. Homogenization of modified milks would, therefore, seem to increase their efficiency if used in cases in which there is no marked intolerance for cow's fat.

There are other fats and oils, besides olive oil, which I am planning to use as substitutes for cow's fat. Cod liver oil, for instance, homogenized with fat-free milk, or malt soup mixtures is fairly palatable as compared with ordinary methods of administration, but I have not yet tried it in a case of difficult fat digestion. Banana oil and the oil of the soja bean might also be tried.

Tonight I wish to call your attention to two cases only, which were my first selected difficult cases, both over two years of age, showing in one case, extreme, in the other, considerable, emacia-

tion, with intolerance for fat and failure to respond to the usual resources of feeding.

CASE 1. E. C. Age, 2½ years. Date of admission, Jan. 23, 1915.

Family History. Negative.

Past History. Instrumental delivery. Birth weight 9-10 pounds. Put on barley water and milk. Was kept on this for three months. Was then given milk, bread and butter. First teeth at 4½ months. Talked at 8 months. Walked at 1 year.

Present Illness. Five months ago began to vomit immediately after eating. Vomiting persisted. Child was put on Walker-Gordon formula for three weeks. Vomiting ceased. Then put back on bread, potatoes, butter and beef juice. Did not vomit. Two months ago vomiting began again. Diet changed frequently without relief. Abdomen became large one month ago, swelling would be noticeable for a day or two then would disappear. Has remained swollen the last three weeks. Bowels constipated, not remarkably. Swelling of hands and feet for the past two weeks. Losing weight for past four months. Frets a great deal. Appetite is good, no urinary symptoms.

Physical Examination. W. D. and P. N. Loss of weight evident. Very irritable, pale. *Head:* Normal. Eyes normal. Ears negative. *Mouth:* Teeth 6/6. Tongue moist and clean. Throat clear. *Neck:* Normal. Glands not enlarged. *Chest:* No rosary. Lungs normal. Heart normal. *Abdomen:* Distended, tympanitic. No masses, tenderness or fluid. Liver and spleen not felt. *Extremities:* Reflexes normal. Slight firm edema of both hands and feet, also of arms reaching just below elbows. *Skin:* Clear. W. B. C. 15,000. Hemoglobin 40%. Von Pirquet negative.

Jan. 24, 1915. Stool, light grey non-formed, undigested potato. Acid reaction. No curds. Micro. Large excess of starch. Great excess of soap and fatty acid.

Jan. 25. R Low fat and low starch diet. Urine normal.

Jan. 31. Stool—light yellow, partially formed, saline like, slightly acid reaction. No curds. Micro. No neutral fat, no fatty acid. Considerable fat as soap, no starch. Persistent loss of weight and persistence of edema.

Feb. 1. Put on olive oil milk, 1.50 olive oil, 5.00 maltose, 1.75 protein, 0.75 barley starch, 5.00 lime water.

Feb. 2. Hungry, No vomiting. R 9 oz. 6 i. d. Barley jelly, b. i. d.

Feb. 5. Stool—large, soft, non-formed, light yellow. Few small, soft, yellow curds, faintly acid. Micro. Considerable neutral fat, no acid, no soap, no starch.

Feb. 6. Color better. Disposition greatly improved. Takes food eagerly. No vomiting. Bowels 1 to 2 i. d. Has lost 12 oz. since put on special mixture, probably due to absorption of edema, as the swelling of hands and feet has disappeared.

Feb. 8. Stool—light yellow, non-formed, saline-like. Few fat curds. Alkaline. Great excess of neutral fat.

Feb. 9. Gained 8 oz. last three days. Takes food easily, looks much brighter, better color.

Feb. 11. Stool—reaction acid. Moderate excess of neutral fat, no soap, no starch.

Feb. 12. Gain of 4 oz. daily for the last 7 days. Acts happy. Color better.

CASE I.

Feb. 15. Stool partially formed, yellow. No curds, alkaline, small amount of neutral fat.

Feb. 15. Sore tongue. Normal temperature. Skin clear. Gained $1\frac{1}{2}$ pounds since put on special milk. Stools 1 to 2 i. d.

Feb. 18. Tongue much better. Stool—formed, yellow, no curds. Alkaline. Slight excess of neutral fat, no soap, no starch.

Feb. 20. Gained 8 oz. last four days. Hungry. Amount of fat in stools is gradually decreasing without cutting down the amount of fat in the milk. Patient actually smiled today.

R Barley jelly, two tablespoonfuls, b. i. d. Zwieback, one slice b. i. d.

Feb. 22. R 2.00 olive oil, 5.00 maltose, 1.75 protein, 0.75 barley starch, 5.00 lime water.

Feb. 23. Stool light yellow, formed. Salve-like. No curds. Alkaline. Small amount of neutral fat, no fatty acids, no soap, no starch.

The net gain in three weeks since starting the homogenized olive oil malt soup mixture has been 2 pounds and 8 oz., an average gain of nearly 2 oz. a day. The disposition, appetite and general appearance of the child has improved in a corresponding degree.

CASE 2. E. D. Winchester, Mass. Seen on Aug. 31, 1914. Age, 22 months. Birth weight $7\frac{1}{2}$ pounds. Present weight 15 pounds 3 oz. First child. Breast-fed for 7 weeks, i.e. from Oct. 28 to Dec. 19, 1913, with a gain of about one-third pound only. From Dec. 19, 1913, to May 1, 1914, was given modified milk with many different formulae, containing sugar of milk, dextrin maltose, Mellen's Food, etc. The net gain in four months was about $1\frac{3}{4}$ pounds. From May 1 to Aug. 26, 1913, was nursed by a wet nurse with a gain of 7 pounds. An attempt to introduce broth and cereals

at this time (10 months) resulted in a sharp intestinal indigestion with the loss of one-half pound in weight. For the remainder of the year, breast milk only was given and the baby reached her maximum weight of 15 pounds 14 ozs. at 12½ months.

The history of the feeding in the second year was one of unsuccessful attempts at weaning, resulting in an irregular but, on the whole, persistent loss of weight, until at the age of two years the weight had dropped to 13 pounds 3 ozs. The appearance was then that of a child mentally bright, but extremely emaciated and without signs of any organic disease. The von Pirquet reaction was negative. The stools were large in amount, of foul odor, with much free fat, fatty acids and soaps. During the second year, all the resources of several experienced pediatricists had been tried and types of feeding adapted to suit various theories which were held as to the cause of the indigestion and malnutrition. These included skimmed milk and fat-free malt soup mixtures, low fat malt soup mixtures, whole milk, goat's milk, and one period of six weeks on a general infant diet, without any milk. The results were much the same inasmuch as temporary periods of gains in weight would be followed by attacks of intestinal indigestion with rapid loss of weight, generally to a new low point.

On November 26 I first tried an homogenized milk with 2.00 fat (cow's), 5.00 maltose, 1.75 protein, 0.75 barley starch, 10% to the total mixture lime water, heated to 212°. With this was given, as before, the broth cultures of the bacillus lactis bulgaricus, and also panopticon. This resulted in a considerable improvement in appetite and a steady gain in weight of one-half pound in a week. Then came the usual "blow up," which differed from others only in that there was no marked intestinal indigestion; but the weight dropped to 13 pounds 3 ozs. again.

On Dec. 5, I used for the first time the olive oil malt soup mixture, starting with 1.00 olive oil, 5 maltose, 1.75 protein, and bicarbonate of soda, 2 grains to the ounce. In the following ten days there was rapid improvement, a gain in weight of 22 ounces, and a very striking improvement in appetite and general conditions. So ravenous in fact was the appetite, that the quantity had been increased to 56 ounces and the formula to 2.50 olive oil, 5.50 maltose, 1.75 protein, 0.75 barley starch, 2 grains bicarbonate of soda to the ounce, making 910 calories, or an energy quotient of 179. Then began a period of weight loss lasting for 5 days and reducing the weight to 13 pounds and 9 ozs. Whether this interesting decline was due to excessive feeding or to some disturbance in salt metabolism, brought about by the considerable amount of bicarbonate of soda (2 grains to the ounce) used during the period from Dec. 5 to Dec. 21, is difficult to determine. There was no loss of appetite or intestinal disturbance during this period of declining weight, but the stools showed a slight excess of soap and fatty acids. On Dec. 19, the olive oil was reduced to 1.50%, and on Dec. 20, the soda bicarbonate was omitted, lime water (5%) substituted and the homogenized milk, heated to 212° F. On Dec 21, immediately began a second period of gain in weight and in general condition, which has steadily progressed, in spite of a ten-day febrile attack with bronchitis. From Dec. 21 to Feb. 26 (67 days) the net gain has been 3 pounds and 14 ounces, or practically an ounce a day, on an average. The food has been increased gradually to 2.50

olive oil, 5.50 maltose, 2.50 protein, 0.75 barley starch. Both lime water and heat have been omitted. The stools are normal in appearance, showing no free fat, fatty acids, nor soaps since Jan. 2, 1915. The tolerance for fats and carbohydrates has steadily increased. Cereal jellies, broths and Zwieback have been added to the diet without precipitating a digestive crisis, and the whole appearance is one of rapid and permanent gain in disposition, strength and weight.

These results in the face of twelve months' steady decline under carefully-directed feeding by competent pediatricists, prove beyond any doubt the practicability of olive oil malt soup mixtures in certain selected, difficult cases of feeding. A wide field is open to determine their indications and limitations.

LUETIC BURSOPATHY OF VERNEUIL: REPORT OF A CASE OF THE CONGENITAL TYPE.*

BY WM. PEARCE COUES, M.D., BOSTON.

UP to the time of Churchman's¹ classic article on this subject in 1909, the study of syphilis of the bursae had received but scant attention in America, though it had been written of in France, and had been recognized as of uncommon occurrence. The British writers on syphilis were silent on the subject, as Churchman points out in his article. Richet's classic early monograph on the clinical features of specific arthropathies does not mention specific bursitis. The elder Keys² was the first to call attention to the subject in America, though his article did not receive the attention it deserved, in making the condition generally known. He does not mention the possibility of specific bursitis in congenital syphilis. It was to Verneuil³ that the credit belongs of first describing the conditions of specific bursitis. A few words concerning him are of interest in this connection.

Aristides Auguste Stanislas Verneuil was born in Paris in 1823 and died at Maison Lafite in 1895. He studied medicine in Paris and was an intern of the Paris hospitals. He was appointed assistant in anatomy in 1848, became *aggrégé* in 1853, and was professor of pathology in 1858. Some of his important contributions were Investigations Concerning the Movements of the Heart, in 1852, Anatomy and Physiology of the Venous System in 1853. Verneuil studied the etiology of tetanus and his experimental and clinical studies of tuberculosis were the means of causing the first Congress on Tuberculosis, which was held in Paris in 1888. Among his shorter but important contributions were articles on anthrax of the lip and of the mucous membranes, resection of the hip, and separation of the lower epiphysis of the femur. It does not seem strange

* Read before the meeting of the New England Pediatric Society on Feb. 26, 1915.

that such an acute observer and physician of such broad knowledge should be the one to give bursal syphilis its first definite description.

A few words concerning syphilis of the bursae as a whole, before considering the congenital type of the disease, must be written to give us a clear understanding of the subject. Churchman's case was the only one he was able to find had been observed in the Johns Hopkins Hospital up to 1909. Keys had previously recorded twelve cases. The most common sites of syphilitic bursitis are the elbow, wrist, ankle and knees. The subcutaneous retro-olecranal and sub-aponeurotic retro-olecranal bursae are those to be considered in the recorded case. Churchman has graphically described the condition as follows:—

"The picture then is one of an indolent affection of the bursae. . . The disease is quite independent of syphilitic arthritis, the bursae involved being oftenest those unconnected with the joints" (as in the reported case). "The bursae involved are those most exposed to trauma. But trauma only determines the site which the disease will occupy. . . Specific treatment leads to a prompt and permanent cure. In view of the marked indolence of the condition, and its great similarity to the arthropathies of syphilis, it should be spoken of as a luetic bursopathy of Verneuil." A perusal of the literature on the subject of bursitis since Churchman's paper in 1909 shows that very little that is definite has been added to his masterly article.

SYPHILIS OF THE BURSAE IN CONGENITAL SYPHILIS.

No attention has been called to this subject, though, as Churchman says, there are intimations that the disease exists. Modern works on bones and points are silent on the subject. This is strange, because, as Churchman again points out, congenital syphilis causes in the joints a condition clinically exactly like luetic bursopathy of acquired syphilis (Clutton's⁴ Disease), or symmetrical synovitis of the knees, familiarly known in England as "Clutton's knees." In the eleven cases reported by this author, no mention of the bursae was made. It seems that if they had been involved, they would not have escaped his remark. Diard,⁵ in reporting fifty cases of gumma in congenital syphilis, made no mention of the bursae, but two of his cases are worthy of note. The first, a case of Fournier's at the St. Louis Hospital, a girl of 25, with indubitable congenital syphilis, had developed at the age of 18 a gumma on the left shoulder, destroying part of the deltoid. The lesion partly healed, but later recurred in situ. From our present knowledge of bursal syphilis, it is certainly a possibility that this might have started in the sub-deltoid bursa. Leloir⁶ and Perrin (*Annales Dermat.*, 1883) reported a case of a patient with a family history of lues. At 14 keratitis developed; at 16 there was a swelling

in the right popliteal space as large as a walnut, not painful and sharply defined, which was not adherent to the skin. A bursa might well be the site of this infection. Such indefinite references as the above are all that one finds in the literature.

REPORT OF CASE.

A. H., 13 years of age, was seen at the surgical clinic of the Boston Dispensary, Oct. 28, 1913. The family history obtained at a later date was as follows: Mother living and well; father, who is an actor, not living with the family; one sister and one brother living; the brother has a scar of an old keratitis on the right eye; both the other children small and delicate looking. Patient has had the chicken-pox and measles; no other diseases; never robust; "always something the matter." Last year fractured a toe; was treated for it in the surgical clinic. In August trouble with the right elbow after a fall; there was swelling, disability, which persisted for a time, and then disappeared almost entirely, and then became worse again after the present fall on the elbow.

Present Illness. On Oct. 27 he fell on the same arm while playing; has had considerable pain and disability in the elbow since. Examination showed a fairly well-developed and nourished boy, rather undersized; no obvious signs of inherited syphilis. The right elbow was swollen, particularly posteriorly over the olecranon where there was circumscribed fluid (olecranon bursa). There was some tenderness over the external condyle. The motions of the elbow were limited and painful. At a later examination, two small pieces of loose bone were felt through the fluid of the olecranon bursa; fixation with internal angular splint and sling. From the tenderness in the external condyle region it was at first supposed that there was a separation of this epiphysis or fracture. Radiographs, however, showed the lower epiphysis of the humerus to be normal. Two small pieces of bone were seen over the olecranon region. Nov. 25, getting on fairly well; but fluid persists, an indolent olecranon bursitis.

Extension and flexion much limited, apparently by the fluid in the bursae. No improvement having been made, five weeks after the last injury, operation was done. Shortly before this time, it was noticed that the child fainted at every examination and change of splint. Consultation with the children's medical department; cardiac dilatation and mitral insufficiency was diagnosed. The diagnosis of probable specific myocarditis was later made. Shin bones were very tender to pressure. X-rays of the tibiae showed a slight but definite periostitis. Wassermann negative.

Operation at the Children's Hospital, Boston Dispensary.

On account of the heart condition I opened the bursa under cocaine. A gummy, honey-like material was evacuated, with a small amount of pus. Two small, worm-eaten fragments of bone were removed from the cavity, which did not connect with the elbow joint. The process was found not to be in the joint, but definitely restricted to the bursae, the motions being limited by pressure from the fluid. Incision drained and partly sutured. The slightly blood-tinged, thick, gummy material, together with the pieces of bone, were sent to the City Hospital for examination; but, unfortunately,

the specimen was not properly preserved, and did not reach the hospital in a state fit for use. The larger piece of bone appeared considerably worm-eaten, like parts of a skull attacked by specific disease—the so-called “crâne en vermineuse.” The bursae effected were the olecranon bursae. The process did not extend around to the front of the elbow joint. The wound did not do well. The condition was unsatisfactory, until specific treatment, local and general, was given, when there was magical improvement and the elbow returned to normal in a short time. The case was followed for about six months. There was no return of the fluid and the function of the arm was perfect. The heart condition, which was severe, also improved step by step with the elbow. The child was seen in January, 1915. There is no trouble with the arm; the general health is very good.

CONCLUSION.

There are two forms of gummatous bursitis, which may exist in congenital as in acquired syphilis, one by extension of specific disease from neighboring parts, the bones and joints, and the other class, to which the reported case belongs, primary in the bursa itself. Syphilis of the bursae is probably often unrecognized.

The disease must be differentiated from subperiosteal abscess near the joints (specific osteomyelitis) and from congenital specific arthropathies, such as Clutton's disease. Radiographs will be of great aid in differentiating this trouble from true specific bone disease.

The Wassermann test,—contrary to the general idea that it is 100% positive in congenital syphilis,—may be negative. An x-ray of the shin bones should always be taken (lateral view), when there is a question of specific bursitis, as well as a Wassermann. The x-ray will often give the more valuable information of the two. Traumatism brings the condition to activity.

An indolent bursitis in a child, particularly in such localities as the elbow or knees, with or without traumatism, and with or without obvious signs of congenital specific disease, should arouse suspicion that we are dealing with a luetic bursopathy of Verneuil, and lead to further study of the case, with this in view.

SOME NEW SYMPTOMS IN AMAUROTIC FAMILY IDIOCY.*

By ISADOR H. CORIAT, M.D., BOSTON,

First Assistant Visiting Physician for Diseases of the Nervous System, Boston City Hospital; Instructor in Neurology, Tufts College Medical School.

THE investigations of the last few years on amaurotic family idiocy have been so thorough that its clinical symptoms and its pathology are probably better known than any other organic brain disease of childhood. I wish, however, to call attention to some phenomena of the disease, which have either been completely overlooked or only briefly described. A reference to some of these phenomena had already been given in a previous communication on the disease, and it was only after further study that their importance was fully recognized. These symptoms may be described as follows:—

Explosive Laughter. This symptom was noticed in three cases. In two of these, the mental deterioration was marked. In the first case the symptom appeared about seventeen months after the onset of the disease, in the second case it began as one of the initial symptoms and ceased about ten months later, at which time the child was taken ill with scarlet fever. In the third case it was noticed about six months after the mental dullness first appeared. Whether this explosive laughter is a sign of the mental deterioration, as sometimes occurs in multiple sclerosis or dementia praecox, or due to some thalamic lesion, is impossible to definitely state at present.

Hydrocephalus. This was present in one of my cases, and in one case each reported by Huysmans and Sachs and Strauss.

Bulbar Symptoms. This was present in one case and was shown by drooling of saliva, choking spells, difficulty of swallowing and attacks of apnoea. This child died suddenly from bulbar paralysis.

Nystagmus. Constant lateral and rotary nystagmus was present in three cases, in one of which it persisted during the entire course of the disease.

Hypotonia. In two cases there was a marked flaccidity of the limbs, resembling the condition seen in amyotonia congenita (Oppenheim). Attention was first called to this symptom in amaurotic family idiocy by Kowarski. In some cases reported from Wilna, Russia.

Abnormal Reflex Phenomena. Increased reflex reactions to sound and touch are among the most interesting phenomena of this disease. The unusual sensitiveness to sound (hyper-acusis), which is so characteristic, has long been known and appears to be present in nearly all cases, at least in the early stages, although it may disappear with the increasing mental weakness. This increased sensitiveness to sounds in organic

* Read before the meeting of the New England Pediatric Society on Feb. 26, 1915.

brain diseases was first described by Oppenheim in cases of spastic diplegia, and in some instances it was so marked that even slight noises would cause asphyxia and loss of consciousness. In one of my cases of amaurotic family idiocy in which spastic phenomena were present, this greatly increased sensitiveness to sounds was present in so high a degree that the child would twitch the entire body, the limbs would stiffen and it would show great difficulty in breathing. Another abnormal reflex phenomenon, one which I have not seen hitherto described, was an increased sensitiveness to light or to tactile stimuli. Under these conditions, if the child were touched lightly with the finger on any part of the body, or, as in testing the pupillary reflex, if an electric pocket lamp were flashed suddenly into the eyes, there would follow a sudden muscular starting or twitching of the entire body. This phenomenon strongly resembles the condition seen in a frog poisoned with strychnine and in some respects, also, is like the increased reflex excitability to tactile and acoustic stimuli of decerebrate animals.

Other abnormal reflex phenomena are observed in this disease. For instance, plantar stimulation may cause a tremor of the stimulated leg or a rhythmical contraction of the quadriceps muscle, both of which may be of longer duration than the stimulus itself. A contralateral knee jerk reflex has also been observed, and like the plantar phenomenon, this consists of a rhythmical contraction of the opposite quadriceps and is of longer duration than the initial reflex itself. In one case an attempt at ankle clonus was unsuccessful in eliciting this reflex, but produced instead a rhythmical contraction of the opposite quadriceps muscle, whose duration again outlasted the length of the attempt to produce the clonus. At no time have contralateral Oppenheim or Babinski reflexes been observed. In one case, in which the pupils were unequal, there could be demonstrated a unilateral paradoxical pupillary reaction.

The explanation of these abnormal reflex signs is rather difficult. The phenomena are probably irradiative and show that certain inhibitions in the receptive mechanisms of the central nervous system are at fault. This is easily understood by the widespread nature of the disease and the involvement of nearly all the cells of the central nervous system. The contralateral reflexes and the quadriceps contraction on plantar stimulation are probably caused by an irradiation from the pyramidal tract, since at all levels fibres from this tract bend from their longitudinal course to a more or less horizontal one and by the white commissure reach the opposite side of the spinal cord and pass into the anterior horn.

The prolongation of the reflex discharge after the initial external stimulus (as seen in the knee jerks, ankle clonns and plantar reflex), probably takes place through this irradiation, in which a larger number of motor elements

are thrown into activity than would normally be the case. This irradiation of reflexes thus corresponds to the causes of irradiation in long spinal reflexes, as shown by Pflüger's second law. The increased tactile and acoustic reflex signs, leading to widespread involvement of the muscles in various parts of the body, likewise finds its most satisfactory explanation on the basis of pathological irradiation. Stimuli reach the brain through the peripheral sensory neurones of touch, sight and hearing, become irradiated to the motor centres and strike these with a proportionately greater force. This takes place because the widespread cellular nature of the disease with the mechanical destruction of the neurofibrils removes certain inhibitions which normally exist in the central nervous system, somewhat like the action of strychnine and consequently the amaurotic idiot reacts to stimuli like a strychninized animal.

Reports of Societies.

NEW ENGLAND PEDIATRIC SOCIETY.

MEETING OF FEBRUARY 26, 1915, HELD AT THE BOSTON MEDICAL LIBRARY.

The Vice-president, DR. E. F. CURRY of Fall River, Mass., in the chair.

The following papers were read:

TYPHOID FEVER IN CHILDREN.

By DR. KARLTON G. PERCY, Boston.*

HOMOGENIZED MILK. ITS POSSIBLE USES IN INFANT FEEDING.¹

By DR. MAYNARD LADD, Boston.

LUETIC BURSOPATHY OF VERTEBRIL. REPORT OF A CASE. CONGENITAL TYPE.

By DR. WILLIAM P. COUES, Boston.

SOME NEW SYMPTOMS IN AMAUROTIC FAMILY IDIOCY.²

By DR. ISADOR E. CORIAT, Boston.

DISCUSSION.

DR. MAYNARD LADD: (Dr. Percy's paper.) I think that no one who has not made a study of the statistics of hospital cases can realize the enormous

* Dr. Percy's paper will appear in a later issue of the JOURNAL.

¹ See JOURNAL, p. 13. ² See JOURNAL, p. 18. ³ See JOURNAL, p. 20.

amount of work which has been done in a paper of this sort. Most of the conclusions are in harmony with the general statistical cases. The very low percentage of mortality is, I think, one of the most interesting points and is worthy of special note. Credit for this should be given to the nursing, as no special drug treatment has been used in these cases.

DR. J. L. MORSE: I also want to call attention to the amount of labor which Dr. Percy's paper represents. I once analyzed a series of 284 cases from the City Hospital records, so that I can probably appreciate it better than anybody else here. As I remember, my figures were not very different from those of Dr. Percy at the Children's Hospital. I think that the mortality was somewhat higher. The point which surprised me more than anything else in his results was the relatively low frequency of bronchitis. I should say off-hand that it was more common than it seemed to be in Dr. Percy's cases.

DR. PERCY, in closing: In answer to the question of ileo-colitis, one infant came in who had typhoid and also an ileo-colitis. It ran the usual course of typhoid and was discharged well of the typhoid and the ileo-colitis. Otherwise in this series, in which we have had but few infants, we have had but one other case which could be considered as ileo-colitis and not typhoid. This child was one I reported in my mortality statistics with positive Widal, low white count, and death from pneumonia, otitis, ileo-colitis and toxemia on the thirty-ninth day.

DR. R. M. SMITH: I would like to ask Dr. Ladd if there has been any attempt to finely divide the fat globules in any other mixture than milk?

DR. MAYNARD LADD (replying to Dr. Smith): You can homogenize oils with a barley water or whey mixture perfectly well. In fact you can get the emulsion in almost any kind of a mixture, but the permanency of the emulsion depends a good deal upon the medium you use. Casein forms one of the best media for binding together the fat globules.

DR. F. B. TALBOT: I have been very much interested in Dr. Ladd's paper and am glad to know about anything that is a possible help in some of these very difficult feeding cases, especially in infants over one year old who have a fat or a starch idiosyncrasy, and I would like to ask Dr. Ladd whether, in the process of manufacture of this homogenized milk, where the pressure of 3000 to 5000 pounds is used, that produces heat enough to cause actual sterilization, and whether that is the reason why milk lasts for several months, and whether that is the reason that the curd does not precipitate in the ordinary way that cows' milk curd does?

DR. MAYNARD LADD (replying to Dr. Talbot): There are many things about this process that I do not yet know. I have not found out the maximum temperature to which the milk rises in going through the machine. The temperature of the milk is raised somewhat, but whether it reaches a point as high as 115° F. I do not know. When it comes out finally, it is not as high as that. I should say not more than 110° F. or 115° F. It may be that the heat generated in process of homogenization has something to do with its better keeping qualities, or it may be due, as one chemist has said, to the even distribution of the fat throughout the milk, inhibiting the growth of organisms which seem to thrive in cream, in preference to skimmed milk. As to the effect upon the coagulation, the minute subdivision of the fat would keep the masses of

casein which are formed by precipitation of the rennin from coalescing into hard curds.

DR. CORIAT (closing remarks): I have nothing further to add excepting that this paper is one of a series of a few which I have been working on for several years in a research in amaurotic family idiocy, and I think my theory of the peculiar muscular startling to different stimuli is well borne out by the pathology of the disease.

Book Reviews.

Selected Addresses. By JAMES TYSON, M.D., LL.D., Professor of Medicine Emeritus, University of Pennsylvania. Philadelphia: P. Blakiston's Son and Company. 1914.

This volume consists of a series of eighteen republished addresses on subjects relating to medicine, education, biography and travel, made by the author on various public occasions during the course of his prominent professional career, beginning with his oration at Haverford College in 1884 on "The Requirements of a Modern College Education," and concluding with his remarks at the dinner given him by his friends on his retirement in 1910 from the chair of medicine at Philadelphia. All are written in the author's most attractive literary style and are replete with the growing richness of wisdom and experience. Volumes of this sort, which preserve the essence of a writer's personality for the benefit of his successors, should be most warmly and gratefully received by the medical profession to whom they are dedicated.

The Balneo-Gymnastic Treatment of Chronic Diseases of the Heart. By PROFESSOR THEODOR SCHOTT. Philadelphia: P. Blakiston's Son and Company. 1914.

This volume is a short treatise based on the author's personal experience in the hydrotherapeutic and gymnastic treatment of chronic cardiac affections at Bad Nauheim, Germany. The system employed has been developed by himself and his brother, the late Dr. August Schott. The work is admirably illustrated with 87 figures, including 41 full-page gymnastic poses. In the foreword by Dr. James M. Anders of Philadelphia, a special comment is made upon the recent development of balneo-gymnastic therapeutics, both in Germany and in America, and on their great value in the treatment of certain cardiac conditions. The excellent translation of this monograph is by Dr. S. Lewis Ziegler of Philadelphia.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, JULY 1, 1915.

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*
GEORGE G. SMITH, M.D., *Assistant Editor.*
WALTER L. BURRAGE, M.D., } *For the Massachusetts Medical Society.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

AMENDMENT TO THE MEDICAL REGISTRATION LAW.

FROM time to time during the past year we have noted the progress of the attempted legislation in Massachusetts to regulate the methods of registration of physicians in this Commonwealth, and in another column of this issue we publish the complete text of the amendment recently adopted, which at last secures the desired regulation.

After an almost yearly attempt, covering a period of about twenty years, the Board of Registration in Medicine has just secured an amendment to the medical registration law, limiting the examination for registration to applicants who have received the degree of doctor of medicine, or its equivalent, from a legally chartered medical school having the power to confer degrees in medicine.

Massachusetts is almost the last state in the

Union to adopt such a restrictive measure, but this amendment to the law finally places it in the progressive lines with other states. The legislation was effected only by a struggle between the two branches of the Legislature, lasting through the entire session.

The bill was first passed by the House after much opposition; rejected by the Senate, but on reconsideration was amended; the House refused to concur with the Senate in the passage of the bill in its amended form, and substituted the original bill in place of the amendment. A conference committee from the House and Senate was then appointed, which recommended the passage of the bill, which was finally passed on May 28, and signed by the Governor on the same day.

All efforts of the Board would have been unavailing without the hearty coöperation of Drs. Nickerson and Frothingham of the House, and Dr. Clark of the Senate, and the persistent, determined, and concentrated effort of Dr. A. K. Stone, secretary of the Committee on State and National Legislation. As a result physicians all over the state rallied to the support of this measure, and did efficient work.

This victory will rid the state of applicants who either fail to pass their examinations for graduation from medical schools, or who leave college under the false impression that a degree is of small importance in comparison with a certificate of registration. The restriction will also put a stop to the past method of one medical school which has made the graduation of its students dependent upon their ability first to pass the Massachusetts Board.

THE DOUBLE RÔLE OF CHLORINE IN WAR.

WHEN the history of the present war is written, not the least interesting feature will be the part played in it by medical science. The aspects of the conflict presented to the profession are the sanitary problems involved in the herding together of vast quantities of men, the surgical cases presenting themselves constantly, especially after an engagement, and the hygienic and dietetic questions arising naturally in the

course of a long campaign. Lately, too, the opposing forces have had recourse to what might be termed chemical weapons in the form of asphyxiating gases. Probably the most widely used and the most deadly of these is chlorine.

In point of fact this gas might well be called the Dr. Jekyll and Mr. Hyde of war. It came into prominence during the early part of the conflict as an agent for the sterilization of drinking water. It has undoubtedly been the means of preserving many thousands of soldiers from intestinal disturbances of various kinds. Dropping its habit of an angel of mercy, it now appears in the shape of a demon of destruction.

Several methods are in use in the armies for the preparation of drinking water by the addition of chlorine, but they do not differ in essentials. One part of chlorine is added to from 500,000 to 7,000,000 parts of water, depending on the quality of the latter. The principle involved is the well known power of chlorine to destroy bacteria. The water is prepared by filtering when this is practicable, which is seldom the case in the field. If it is not, then alum is used, which will precipitate most of the organic material which would otherwise vitiate the chlorine. The chlorine is prepared in the usual way and acts upon the water while in its nascent state, thus being rendered more powerful. After treatment there should be an excess of chlorine, which is shown by testing with starch and iodides. Contrary to what might be expected, the resultant drinking water does not taste of the chlorine by the time it is ready for use, at least officers in the field testify that they have had no complaints on this score.

The more nefarious activities of chlorine first came to notice the latter part of April, this year, when the report was circulated that the Germans were using an asphyxiating gas, greenish in color and somewhat heavier than air. This gas was allowed to drift toward the attacking forces when the wind was favorable, or else contained in bombs which were propelled towards the enemy. Judging by the physical appearance of the gas, the symptoms of the men who breathed it and the precautions which were observed to have been taken by the German soldiers who were captured or found dead, the gas used was almost certainly chlorine. The pathological process caused by its inhalation is a severe, purulent bronchitis, and death occurs from asphyxia. In autopsies of such cases edema of the lungs has been a constant finding.

TREATMENT VERSUS CLIMATE IN TUBERCULOSIS.

THERE are two broad classes into which the practitioner usually divides his cases of incipient tuberculosis, either consciously or unconsciously. These are the well-to-do cases and the others. That is, those who can afford to change to a healthier climate and those who cannot.

Having decided after due inquiry that his patient can afford to seek the health belt, the physician should not consider his whole duty done when he advises him to make this change. He should be at some pains to impress upon the mind of the prospective health seeker the fact that the climate itself is not going to cure him unless he gives it every chance. For instance, although it seems scarcely credible, many patients are at considerable pains and expense to transfer their Lares and Penates to the west or southwest and then try to reap the benefits of the climate by taking a walk of an hour or two a day and sleeping with their windows open! Whatever Spartan flavor this may have to the patient, he should be told plainly that he might almost as well stay at home as dilute his treatment thus. The only way to use a climate is to soak it up, to get out in it, every day all day and every night all night. At the same time the other essentials of treatment, rest, diet and medical attention, should be employed.

In the United States Public Health Report for April 23, Dr. Ernest A. Sweet emphasizes this point in the course of an exhaustive report on conditions in Texas and New Mexico. Among other things he says, "The average sufferer comes to the West with the sole idea that the climate will cure him, that all he needs to do is to take up his residence in that particular locality, and that nature will somehow perform a miracle." This sort of invalid has never heard of fresh air, has made no provision for rest and may remain there a year, running a fever all the time, without consulting a doctor.

In fact, it seems to be the general opinion of those who have studied this subject that care without climate is better than climate without care, and this should be impressed on the second class of patients, those who for financial reasons are not able to change their residence. If patients are brought to understand that careful and intelligent attention to hygiene is more important than the climate they happen to live in, there would be fewer cases of depression due to brooding over inability to seek another climate.

EUROPEAN WAR SURGERY.

THE topics in surgery and medicine arising as a result of the events of the present European War are not only many, but of exceptional interest on account of the unusual character of the problems which they present. From time to time during the past six months the JOURNAL has published various contributions from its special correspondents in the European countries, presenting different aspects of the situation there existing from the immediate standpoint of those actually engaged. In the present issue of the JOURNAL we are glad to publish as leading articles two more extended papers based on the work and experience of the American Ambulance Hospital at Neuilly. The first, by the French surgeon, Dr. Gros, discusses particularly the problems of transportation and presents interesting conclusions with regard to the relative merits of various types of motor ambulances and of different methods of handling and caring for the wounded. The second paper, by Dr. Osgood, records the result of his recent experience in dealing with the problems presented among wounded soldiers in his special field of orthopedics. Though dealing with widely diverse subjects, these two articles illustrate the important fact that mechanical and technical skill, inventiveness and judgment, whether in dealing with the motor problems of transportation or with the static problems of apparatus and its adjustment, are essentials in securing the highest service and efficiency. It is our hope in future numbers of the JOURNAL, to present other expert articles dealing similarly with special aspects of the various problems presented in European war surgery.

 MEDICAL NOTES.

PREVALENCE OF MENINGITIS, POLIOMYELITIS, AND OTHER DISEASES IN APRIL.—The weekly report of the United States Public Health Service for June 4, 1915, states that during the month of April, 1915, ten cases of cerebrospinal meningitis, three of poliomyelitis, 478 of smallpox and 67 of typhoid fever were reported in Indiana. During the same month there were in Texas, 386 cases of smallpox and 60 of typhoid; and in the state of Mississippi seven cases of cerebrospinal meningitis, 6078 cases of malaria, 1299 of pellagra, eight of poliomyelitis, 455 of smallpox and 173 of typhoid fever.

BRITISH BIRTHDAY HONORS FOR PHYSICIANS.—Among the British physicians recognized for distinction in the annual award of honors upon the occasion of the King's birthday are Dr. James Mackenzie and Dr. Frederick Needham, who both received the honor of knighthood. Sir James Mackenzie has been distinguished for the great scientific and practical value of his investigations of cardiac physiology and pathology; and Sir Frederick Needham, a well known expert in psychiatry, has rendered many years of able service to the commissioners of the board of control and to the British Lunacy Commission.

AMERICAN SOCIETY OF TROPICAL MEDICINE.—The annual meeting of the American Society of Tropical Medicine was held in San Francisco on June 15. The following officers were elected for the ensuing year: President, Dr. Milton J. Rosenau, Boston; first vice-president, Dr. Abiley K. Ashford, San Juan; second vice-president, Dr. C. C. Bass, New Orleans; secretary, Dr. John M. Swan, Rochester, N. Y.

NATIONAL BOARD OF MEDICAL EXAMINERS.—The plan adopted by the American Medical Association at its recent 66th annual meeting in San Francisco, to provide a National Board of Medical Examiners, is reaching its fulfillment. It is intended that this board shall provide an examination which will entitle those applicants who pass it to practice medicine in any state in the union, that is, that states now requiring examination of applicants for licenses to practice medicine will accept the certificate of the National Board as sufficient. The inconvenience now experienced by physicians in going from one state to another to practice their profession may thereby be avoided. Up to the present time the following men have been appointed to serve on such a board: Admiral William C. Braisted, Surgeon-General, U. S. Navy, chairman; Major-Gen. William C. Gorgas, Surgeon-General, U. S. Army; Gen. Rupert Blue, Surgeon-General, U. S. Public Health Service; Col. Louis A. LaGarde, U. S. Army, treasurer; Asst. Surg.-Gen. W. C. Rucker, U. S. Public Health Service; Commander E. R. Stitt, U. S. Navy; Dr. Herbert Harlan, representing the Confederation of State Boards of Examiners; Dr. Isidore Dyer, representing the Association of American Medical Colleges; Dr. E. Wyllys Andrews, representing the American College of Surgeons; Dr. Lewis B. Wilson, representing the Mayo Foundation; Dr. Victor C. Vaughan, representing the American Medical Association; Dr. William L. Rodman, secretary, representing the American Medical Association.

Dr. Alexander R. Craig of Chicago, secretary of the Association, reports that its membership has increased from 74,235 in 1914 to 76,020 in 1915.

PROHIBITION OF BORIC ACID AS A FOOD PRESERVATIVE.—Report from Washington, D. C., states that on June 21 the United States Supreme Court upheld the constitutionality of the Illinois Pure Food Law which prohibits the sale of a food preservative containing boric acid. Justice Hughes in his decision, stated that the validity of the law must be upheld unless it were shown beyond doubt that boric acid as a food preservative is not unwholesome. This, the court held, had not been done.

MEDICAL EDUCATION IN CHINA.—Report from Baltimore states that Dr. William H. Welch left that city on June 30 for San Francisco, whence he will sail on August 1 to China with Dr. Simon Flexner of New York and Dr. Wallace Buttrick, director of the China medical board and secretary of the general education board. The board composed by these physicians has been established by the Rockefeller Foundation to carry out the numerous recommendations of a special commission, which last year made an elaborate study of the conditions of public health and medical education in China. Its purpose is to systematize medical education in that country and to establish throughout it a series of American hospitals to be administered by American physicians and surgeons. To this end the Foundation has recently purchased for \$200,000 from the London Missionary Society, the Union Medical College at Peking, and the first action of the China Medical Board will be to take over this institution and develop its work.

"Independent of the acquisition of the Peking College, which the Foundation recognizes as its most important activity, the China Medical Board has made an appropriation of \$16,000 a year for five years to the Yale Medical College at Chang Sha, and has appropriated \$16,000 for one year to the Harvard Medical School at Shanghai, and also has appropriated similar sums to several missionary hospitals."

SUIT ON BEHALF OF TYPHOID VICTIMS.—In various issues of the JOURNAL during the fall and winter of 1913-14 we noted from time to time a serious epidemic of typhoid fever which arose in Rhode Island as the result of an excursion of a party aboard the steamer *Rochester* to the celebration of the Perry centennial at Buffalo, N. Y., in September, 1913. On June 18, 1915, a libel suit for \$265,000 damages was entered on behalf of forty-five residents of Rhode Island, victims of this epidemic, against the navigation company owning the *Rochester*. In this suit the company is charged with negligence as a result of which the epidemic occurred. At the time it was considered that the infection was due to impure drinking water provided aboard the steamer.

EUROPEAN WAR NOTES.—In the issue of the JOURNAL for June 17 we noted the critical condition of the King of Greece and the operation which was performed upon him for empyema. It has recently been reported that Dr. Richard P. Strong of the United States Public Health Service, now in Serbia, in charge of the American Red Cross typhus fever commission, was also summoned to see the king in consultation. It has recently been announced from Amsterdam by way of London that the king's other two consultants, Dr. Friedrich Kraus of Berlin, and Baron von Eiselsberg of Vienna, left Athens on June 19 giving a favorable prognosis of his condition.

The weekly report of the United States Public Health Service for June 18 states that during the week ended April 24, 1915, there were 347 cases of typhus fever in Austria-Hungary, chiefly among soldiers, prisoners and persons from Galicia. In Germany during the week ended May 8 there were 61 cases of the disease among German soldiers. Typhus is also reported as present among Russian prisoners in eleven districts and in Saxony.

On June 26, the totals of the two principal New England relief funds for the European war reached the following amounts:—

Belgian Fund.....	\$264,468.26
Red Cross Fund.....	135,275.16

BOSTON AND NEW ENGLAND.

BOSTON DISPENSARY CLINICS.—A change is announced in the hours during which patients may be admitted to the morning clinics at the Boston Dispensary. Hereafter the doors will be open from 8.45 to 10.30 A.M., instead of from 9 to 11.

SMALLPOX IN NEW BEDFORD.—There has been recently a slight outbreak of smallpox at New Bedford, Mass. Since May 15 there have been ten cases and three deaths from the disease. All the patients were natives of Cape Verde. Only two of them had ever been vaccinated and except in these two cases the disease was of the most virulent type, four of the cases being hemorrhagic.

AWARDS TO MASSACHUSETTS HOSPITALS.—The recently published bulletin (No. 10) of the Massachusetts State Board of Insanity announces that at the meeting of the American Medico-Psychological Association at Old Point Comfort, Va., May 11 to 14, the committee on diversional occupation of the insane announced that in 1912, 6 hospitals took part in the exhibit held by the association; in 1913, 12 hospitals; in 1914, 14 hospitals; and at the present meeting, 1915, 32 institutions were represented. Of these 32 contributing institutions, 13 were from Massachusetts, 12 of these being State institu-

tions and one a private hospital. Awards were made by the committee. Fifteen certificates were awarded to Massachusetts institutions, three each to the Taunton and McLean Hospitals, two each to the Danvers and Gardner Hospitals and one each to the Worcester, Northampton, Westborough, Boston and Grafton Hospitals.

NEED OF FUNDS FOR THE INFANTS' HOSPITAL.

—In the issue of the JOURNAL for May 27, 1915, in reporting the work of the Infants' Hospital for the past year, attention was called to the need of this institution for an increased income, that the important service which it so efficiently renders to the medical and charitable work of the city should not be seriously handicapped. There are very few places with facilities for taking care of poor babies of the city. The Infants' Hospital is especially fitted for work of this character yet, because of lack of income, it has been obliged to refuse admission to an average of three babies each day. The hospital has a capacity of 65 beds and the estimated cost of running it at full capacity is \$28,500 a year. With 24 beds last year the cost was \$24,000. That is, an increase of one-fourth in the income will treble the work of the hospital. It is to be hoped that the generosity of its friends and well-wishers may enable it to realize its opportunities to their fullest capacity.

DR. CREEL AS BOSTON HEALTH COMMISSIONER.

—In the issue of the JOURNAL for May 13 we announced the acceptance by Dr. Richard H. Creel of the United States Public Health Service of the appointment as health commissioner of the city of Boston. In the issue of the JOURNAL for June 10 we published a further statement containing a letter from Dr. Creel in which he expressed the necessity of his declining this appointment on account of his health. It is now announced (on June 21) that Dr. Creel has decided again to reconsider his action and will accept the appointment as health commissioner of the city of Boston, for one year, beginning his duties in this position today, July 1. His salary is to be \$7500 a year.

TRAINING OF DENTAL NURSES.—At a meeting of the Massachusetts Dental Association in Boston on June 21, it was announced by Dr. Eugene H. Smith that during the ensuing year the Harvard Dental School will establish a course of instruction for dental nurses, since the registration of the latter has been provided for by recent legislation.

Dr. Charles F. Painter, also announced the appointment of a committee, on the part of the Tufts Dental School, to confer with a Harvard committee on the subject of courses in dental hygiene.

REPORT OF BOARD OF HEALTH OF WORCESTER, MASS.—The annual report of the Board of Health of the city of Worcester shows that for the year 1914 there were reported 349 cases of measles with 18 deaths, 313 cases of tuberculosis, 280 cases of diphtheria, 186 cases of scarlet fever with 5 deaths, 149 cases of ophthalmia neonatorum and 75 cases of typhoid fever with three deaths. The mortality rate for the year is 14.16 which is the lowest rate which the city has had during the last half century.

OPENING OF EVERETT TUBERCULOSIS HOSPITAL.

—On June 18 the new tuberculosis hospital erected by the city of Everett was opened for inspection. The hospital will accommodate 24 patients and is intended to care for advanced cases and those patients in the early stages of the disease who are awaiting admission to the state sanatoria. It is stated that a total of 75 cases has been reported to the board of health of the city. Adjoining the hospital is another building to be used for the admission of patients with other communicable diseases.

HONORARY DEGREES FOR PHYSICIANS.—Among the honorary degrees conferred on graduates at the recent commencement of Yale College is that of B.Sc. on Dr. Charles Wardell Stiles of the United States Public Health Service for his work in connection with pellagra and the hookworm disease.

At the commencement of Harvard College, on June 24, honorary degrees were conferred upon two physicians as follows:—

MASTER OF ARTS:

ALEXANDER HAMILTON RICE, explorer of tropical America, adventurous and hardy, who heard the wild call of nature and revealed her hiding place.

DOCTOR OF SCIENCE:

FRANK BILLINGS, physician and citizen of Chicago; powerful in his profession and his community, who has inspired medical research, improved medical administration in his own State and promoted a higher grade of medical education throughout the land.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending June 15, 1915: Diphtheria, 68, of which 4 were non-residents; scarlatina, 105, of which eight were non-residents; measles, 221, of which 1 was non-resident; tuberculosis, 82, of which 2 were non-residents. The death rate of the reported deaths for the week was 15.59.

MOUNT SINAI HOSPITAL.

Through the generosity of an anonymous donor, a lectureship has been established at the Mount Sinai Hospital named after the late Dr. Edward G. Janeway, who was for many years associated with the medical staff. The foundation has been created for the purpose of inviting important investigators to present the results of their work to the staff of the hospital.

Massachusetts Medical Society.

ANNUAL MEETING OF THE COUNCIL.

JUNE 8, 1915.

The annual meeting of the council was held at the Copley-Plaza Hotel, Boston, June 8, 1915, at twelve o'clock noon. The president, Dr. Charles F. Withington, was in the chair, and the following 116 councillors present:—

FAIRFAX, E. E. Hawes, M.N.C.
C. W. Miliken.

V-P., Vice-President *ex-officio*.
M.N.C., Member Nominating Committee.
C., Chairman of a standing committee.

The minutes of the last meeting were read and accepted.

The names of the Nominating Committee were read by the secretary, and the committee retired.

Dr. C. M. Green read the following report:

THE COMMITTEE ON MEMBERSHIP AND FINANCE makes the following recommendations:

1. That the following-named Fellows be allowed to retire, under the provisions of Chapter I Section 5, of the by-laws:

Hood, Mary Gould, of Newton Centre.
MacMillan, Andrew Louis, of Hanover.

2. That the following-named Fellows be allowed to resign, under the provisions of Chapter I, Section 7, of the by-laws:

Albert, Lionel Louis, of Central Falls, Rhode Island.
Cumston, Charles Greene, of Geneva, Switzerland.
Graustein, Charles Israel, of Brockton.
Mitchell, Mary Paulsell, of Warren, Pennsylvania.
Porter, William Townsend, of Dover.
Wood, Mary Anna, of Pittsfield.

3. That the following-named Fellows be allowed to change their district-membership without a change of legal residence, under the provisions of Chapter III, Section 3, of the by-laws:

Alexander, Thomas Branch, of Scituate Harbor, from Plymouth to Norfolk South
Breslin, John George, of Charlestown, from Middlesex South to Suffolk.
Bryant, John, of Cohasset, from Norfolk South to Suffolk.
MacCallum, Wallace Peter, of Dorchester, from Norfolk to Suffolk.
Parks, Edward Luther, of Roxbury, from Norfolk to Suffolk.
Schirmer, Joseph Walter, of Needham, from Norfolk to Suffolk.
Smith, George Carroll, of Norfolk District, from Norfolk to Suffolk.

For the Committee on Membership and Finance,
CHARLES M. GREEN, *Chairman*.

Voted, To accept the report and adopt its recommendations.

The reports of the committees appointed at a previous meeting to consider the petitions of the following named for restoration to the privileges of fellowship were acted on favorably: F. X. Mahoney, J. A. Ceconi, E. O. Tabor, C. H. Phillips, J. J. Sullivan, R. F. Burns. Petitions of the following named to be restored to the privileges of fellowship were assigned to committees of three each: F. H. Lally, A. V. Lyon, Ada H. Tedford, S. H. Rubin.

Dr. H. C. Ernst read the following report and it was accepted by vote:

I beg to present herewith the report of your COMMITTEE ON MEDICAL EDUCATION AND MEDICAL DIPLOMAS for the past year.

Your delegate attended the Eleventh Annual Conference of the American Medical Association on Medical Education and the meeting of the Association of American Medical Colleges, which was closely associated with the meeting of the Federation of State Medical Boards of the United States. These meetings took place in Chicago on February 15, 16, and 17, 1915. The programs are herewith appended.

Perhaps one of the most interesting contributions was that of Dr. Henry S. Pritchett on "The Classification of Medical Schools," the full suggestion of which can be obtained only by reading the article itself. (*Journal of the American Medical Association*, Vol. lxiv, No. 12, p. 961.) The gist of it is a criticism of the methods followed and the results obtained in the classification under their headings A plus, A, B and C as published by the Council on Medical Education. The tenor of the contribution is indicated by the first paragraph and the conclusion, the former of which reads as follows:

"The desire to classify seems to be a universal human motive. In education, in politics, in society, men reach out for some form of classification that shall be definite and specific, so that every cause may have its right label, every party its true name, and every institution be included in its proper class."

Before quoting the conclusion, this question and answer furnishes further indication of the tenor of the paper:

"Can medical schools, any more than colleges, be classified into sharply divided classes? This question lies at the root of the whole matter. In reply I would say that, in my judgment, nobody is so well prepared to carry out such work as a body which represents the medical profession. Reform in medical teaching, like all other reform which is genuine, will come from within, not from without. No other group of men, in my judgment, could hope to do what the Council on Medical Education has accomplished. I believe, as I have already said, that the Council has suffered in its work by a lack of touch with the educational conditions with which it has been dealing. It can, I believe, improve its future legislation by availing itself of a closer knowledge of schools and colleges, but I question whether any group of men, however qualified, can make a hard and fast classification of medical schools which would not be open to serious criticism. In other words, the problem of classifying schools into four or five groups on such criteria as the Council has assumed seems to me practically insoluble. It has served its day and some looser form of grouping seems now desirable."

The conclusion states the matter from a very broad point of view:

"Let me say one word in regard to such criticism as I have made of the Council on Medical Education. I have spoken concerning the work of the Council with great frankness for the reason that no other course is worth following, and in the belief that progress comes only by the frank and honest expression of opinion in regard to such matters. I have such high regard for the work of the Council and for the work of its Chairman that I take a keen interest in the preservation and development of the Council's work—a work which seems to me liable to fall from its own weight if the classification proceeds along the present lines. I hope, as a layman in medicine, that it is not impertinent of me to discuss these matters, since they are primarily questions of education, and I hope also that it may be admitted that the sincerest service a friend can perform with respect to the work of the Council is to speak in a critical, and yet in a friendly way concerning those directions in which, it seems to him, the dangers lie. The interests of

education in our nation are one. Education itself is one thing, from elementary school to university, and medical education in its largest and truest sense can be approached wisely only when one keeps this fact in view and regards medical education in its true perspective as a part of the whole problem of education of the American nation."

This undoubtedly was the most important of the contributions to the meeting of the Association of American Medical Colleges.

Another discussion of interest that took place was that which considered some fallacies in the arguments against full-time clinical instruction, the matter being opened by Dr. M. G. Seelig of St. Louis. It cannot be stated that the feeling of the meeting was much influenced by this discussion, but the special point in favor of the procedure is made in the observation that "those who favor the plan of full-time clinical instruction are influenced in no small part by the hope that the properly qualified clinical teacher will foster, stimulate and direct clinical research of a higher order than is commonly produced at present. To encourage scientific clinical research, therefore, the clinical teacher must be provided with an environment as favorable as that of the fundamental teacher."

The more important parts of the program of the Conference on Medical Education were made up by the report of the Committee on the Reorganization of Clinical Teaching, presented by Dr. Victor C. Vaughan; that on the University and Higher Degrees in Medicine, presented by President George E. Vincent of the University of Minnesota; and that on Courses and Degrees in Public Health Work, presented by Professor M. J. Rosenau of Boston.

The methods by which clinical teaching is to be improved is considered in the report under the following headings:

1. The provision of adequate hospital and dispensary facilities.
2. The need of an adequate financial income.
3. The readjustment of the place in the curriculum in which prescribed clinical instruction shall be begun.
4. The use of the dispensary.
5. The organization of the hospital units.
6. The utilization of students as clinical clerks in hospital wards.
7. The utilization of special and extramural hospitals.
8. In the co-ordination of departments in teaching.
9. The limiting of the practice of the clinical teachers.

And in conclusion the writer of the report says:

"Whatever may be said regarding the practicability of limiting the practice of clinical teachers, the other propositions dealt with in this paper have to do with improvements which are well within the reach of the majority of medical colleges. To construct a reasonable working standard for immediate adoption, and another, more ideal standard, for adoption sometime in the early future is the chief function of this Committee on the Reorganization of Clinical Teaching. (*Journal of the American Medical Association*, Vol. lxiv, No. 10, p. 785.)

In taking up the matter of higher degrees in medicine, President Vincent recognizes the practical difficulty encountered by those interested in this subject—that of differentiating between the requirements of graduates in medicine, who need what may be called "brushing-up" courses and those who wish to pursue a serious line of study in some specialty in medicine, which is worthy of the same recognition that is given to similar efforts leading to the higher degrees in academic departments of the universities—Ph.D., for example. It is only for these latter that the present existing higher university degrees should be considered, and whether or no it is advisable to establish and to grant degrees in specialties is a matter that is still open to serious consideration and discussion. (*Journal of the American Medical Association*, Vol. lxiv, No. 10, p. 790.)

The contribution of Professor Rosenau on Courses and Degrees in Public Health Work embodies a description of the work being carried on in Boston by the School for Health Officers, an enterprise conducted by Harvard University and the Massachusetts Institute of Technology, acting in co-operation through an Administrative Board appointed for this purpose by both institutions, and emphasizes the fact that public health work is becoming a separate profession, and that public health service, as a career, must be made an end in itself. (*Journal of the American Medical Association*, Vol. LXIV, No. 10, p. 794.)

These were the points that especially attracted the attention of your delegate at the meetings in Chicago.

So far as the work of your Committee has concerned itself with medical diplomas, it is well to say that, in accordance with the vote of the Council passed in June, 1914, "that the Committee on Medical Education and Medical Diplomas has power to recognize a medical degree coming from a not recognized medical school, presented by a candidate for Fellowship in The Massachusetts Medical Society, provided such candidate has practised in a given locality for a minimum of five years, has proved himself to be a skillful and conscientious practitioner of medicine, and is recommended by a number of his neighbors who are already Fellows of the Society," a number of holders of such degrees have been approved for examination by the Censors. The Committee has adopted the following form of vote to cover these cases:

"Voted: To recognize the degree of of for the purposes of his examination by the Censors for Fellowship in the Massachusetts Medical Society. The action of the Committee was based upon information received in letters written by Fellows of the Society endorsing 's professional and personal qualifications."

The Committee desires to remind the Secretaries of the District Medical Societies that the Council has vested the authority to approve holders of these non-recognized diplomas in the Committee on Medical Education and Medical Diplomas and not in the Secretaries of the District Medical Societies and that, if the Secretaries will recognize this fact and submit the credentials of applicants holding these non-recognized degrees to the Committee before allowing the holders to come up before the Censors for examination, some confusion and delay may be avoided in the future. Respectfully submitted,

HAROLD C. ERNST, *Chairman*.

Dr. A. K. Stone presented the accompanying report and it was accepted:

THE COMMITTEE ON STATE AND NATIONAL LEGISLATION respectfully reports on its activities during the year as follows:

The Committee has had a busy year. The 1914 legislature did not adjourn for nearly a month after the annual meeting of the Society, and it was a very strenuous time for the Committee, with legislative hearings and conferences regarding the reorganization of the Department of Health. The bill which finally passed the Legislature, while it was by no means the complete act which had been drawn by Dr. Rosenau and considered and amended by your Committee, nevertheless accomplished the main objects for which legislation was desired, and enabled the new department to start on a much better business basis than was possible under the previous law. Governor Walsh kept the letter of his promise made to the Society in his speech at the last annual dinner, and the Committee was frequently in conference with him until he selected Dr. Allan J. McLaughlin, of the U. S. Public Health Service, for the position of Commissioner of Health; and later, when he selected the Advisory Council, which consisted of William T. Sedgwick of the Massachusetts Institute of Technology, George C. Whipple, a sanitary engineer of Harvard, David L. Edsall, Harvard Medical

School, William J. Gallivan, of Boston, Joseph E. Lamoureux, of Lowell, and Milton J. Rosenau, of the Harvard Medical School. The whole attitude of the Governor toward the reorganization of the Health Department was on the high plane of public efficiency.

Too much praise cannot be given to Dr. E. H. Bigelow, of Framingham, for his work in the Legislature, where his never-failing patience, persistence and good nature had much to do with making this legislation possible.

With the entrance of the Legislature of 1915, new work at once began. The dominant political party decided that as far as possible it would undertake no new legislation, that it would create no new commissions, that there were certain problems that must be settled, and that when these and the appropriation bills were passed, the Legislature would adjourn. To a great extent this program has been adhered to. While it was easy to have undesirable legislation killed off, it was at the same time more difficult to have desirable legislation considered.

As a result of this, and because many health laws had been passed during the past few years, there were fewer measures than usual which concerned the attention of the Committee, but several of these were, nevertheless, of much importance to the medical profession.

There were about thirty measures which were considered by your Committee. Some of these were opposed either by letter or by appearing in opposition before the appropriate committee. In like manner it was voted to approve of a certain number of measures, either directly or by letters which signified the approval of the Committee to the persons who had the measures actually in charge.

The usual bills were introduced to make special provision for irregular practitioners, and one of these which was designated (as its proponents frankly acknowledged) for special legislation for one individual: a so-called Chinese doctor. This bill was pushed and fought for with a most singular determination which was a marked commentary on the grip that the irregular in medicine has upon the minds of many people.

There was the regular anti-vaccination bill, which was defeated more easily than last year. An anti-vivisection bill made its appearance and was met by the men from the medical schools most interested in this question.

One measure was aimed directly at the Massachusetts Medical Society. On petition of one John J. Tallant, a bill was introduced that all registered physicians should be eligible for membership in all chartered state medical societies. This bill was supported by a member of this Society, who was a professor in the College of Physicians and Surgeons Medical School.

The tuberculosis legislation of the state was attacked by several minor bills, early in the session. These made no headway at the time, but in the last days of the session, a more determined move was made by certain cities that wished to avoid compliance with the law. When, however, the true facts of the case were presented to the various legislative committees, they, by a resolve which was passed by both branches, referred the matter of hospital construction in the case of the smaller cities to the Department of Health, to report upon to the next Legislature. In the meantime, it is hoped that the plans already made for compliance with the law relative to hospital construction will be carried out by many cities, so that there will be only a small number of communities which will have to be arranged in groups by the Department of Health; for it seems to your Committee that this is primarily a municipal question, and rarely one that can be solved by a group hospital.

During the year, the so-called Harrison Anti-narcotic Act was passed by Congress, and went into effect on March first. Your Committee had correspondence with the senators regarding certain amend-

ments to this act which should make it less onerous in its working as far as the practitioners of medicine were concerned. Later, it was found that the State law regarding narcotics was much at variance with this act, and that it was desirable to modify the State law so as to conform to the reading of the Harrison Act. This was done with the addition of cannabis indica to the drugs which must be reported, as it was thought that there were signs that dope fiends were, under the increasing difficulties of securing opium and cocaine, shifting to hashish. During the process of legislation on this anti-narcotic law, an event occurred which showed what a power the medical men have if they are really in earnest on a legislative matter. The physicians of the state received a circular from a drug firm, calling attention to a variation in the proposed law from the actual reading of the Harrison Act. It was really not an important change, although it was much better that the Harrison Act should be followed, and it was so understood at the conference which I and others had had with the committee of the Massachusetts State Pharmaceutical Society, which was directly responsible for this legislation. The statements in the circular I refer to were overdrawn as to the effect on the physicians, but the medical men became aroused and letters poured in at the State House in such numbers that the sponsors of the bill quickly saw that something must be done at once to save it; and after several hurried conferences, the bill was withdrawn from the house and amended in committee. Such is the effect of united medical action. It is one reason why our friends, the Christian Scientists, anti-vaccinationists and various irregular practitioners are more powerful than the regular profession; they appear in clamoring hordes and are opposed by the well-known small group of members of your Committee.

The Massachusetts Dental Society secured the passage of an act to revise the law relative to the practice of dentistry and they are to be congratulated on this result.

A bill for the amendment of the laws regulating the practice and registration of nurses failed to get by the Committee because the nurses and the medical men and the interested general public are not agreed as to what is desirable in the way of legislation. Therefore the legislators prefer to keep the present inadequate law until some common agreement can be reached.

The so-called Clean Milk Bill, introduced by the Central Labor Union, was a simple bill for the protection of the consumer, by placing the responsibility for the production of milk in the hands of local boards of health or the State Department. There was criticism that there was no penalty and no provision for the expenses of inspection, and in certain cases there might be a clash in authority between the local boards and the State Department of Health. This bill, amended to meet the requests of the agriculturalists, was passed, only to be vetoed by the Governor, who was influenced by the violent opposition of many dairymen who threatened to go out of business if the bill were passed, and to make the state practically dependent on out-of-state dairies in the immediate future.

Previous to this, propositions from the Governor and others to have a new commission to study the milk question, were turned down by the legislature in accordance with the caucus vote that there should be no new commissions this year. It may be well to remark that the medical men in the legislature were not united in their attitude regarding milk legislation.

The most important positive act of constructive legislation that passed this year was that by which any person wishing to be registered in Massachusetts as a physician must henceforth be a graduate of a properly incorporated medical school. Massachusetts was the third state this year to pass such a law, Tennessee and Washington being the other

two, and Massachusetts was the next to the last state in the Union to make this requirement. Colorado is now the only state left without such a law. The success of this measure was due to the indefatigable work of Dr. Bowers, the secretary of the Board of Registration, while in the Legislature, Dr. Nickerson of Harwich and Dr. Frothingham of Lynn did hard fighting on the floor of the house and much personal work in both branches of the Legislature. The profession at large had also much to do with the final result, for they let their opinion be known in no uncertain manner to their senators and representatives; especially was this so in New Bedford, Fall River, Cambridge, Boston and Lawrence.

The work in many respects has been discouraging, because in spite of the good work of Dr. Hart, the House Chairman, and of the energetic work of Dr. Nickerson, who has won a strong position in the house during this, his first term, the Public Health Committee has not had the influence it should. It was rarely that more than five men attended the hearings; in fact, several men practically never were seen, and the chairman had to poll the committee in the lobbies and anterooms, rather than in the committee room. It is to be wondered at that the few active members were able to do as well as they did, and they deserve much credit for all that they accomplished.

The thanks of the Committee are due to the forty members of the Auxiliary Committee, many of whom worked hard to make their senators and representatives realize medical opinion, and often were able to direct the expression of general public opinion in favor of sound public health measures.

Respectfully submitted,

ARTHUR K. STONE, *Secretary*.

Dr. M. J. Rosenau read this report and it was accepted:

ANNUAL REPORT OF THE COMMITTEE ON PUBLIC HEALTH.

The Committee on Public Health presents the following report:

Owing to radical changes in the health administration of the state, the Committee has considered it wise to follow a waiting, rather than an aggressive policy, throughout the year, feeling that by doing so, a more helpful campaign might be made later when the plans of the State Commissioner of Health were better understood and intelligent cooperation more easily established. It was also thought better not to push health legislation this year, because of a similar decision by the Commissioner of Health and the Public Health Council.

It is the unanimous opinion of the Committee on Public Health that perhaps the most pressing need is for competent health officers throughout the Commonwealth. There should be a qualified sanitarian in each city, town and rural district, to guide and instruct the people in the art of hygienic living and to administer the health laws. The Committee has, therefore, in all its work throughout the year, endeavored to emphasize this point and to stimulate action along these lines. Several full-time and specially trained health officers have been appointed, notably at Waltham and Watertown.

Letters have been sent to the secretary of each county district medical society asking that talks be given to the public on various matters relating to public health, such as the prophylaxis of typhoid fever and other communicable diseases, the discussion of infant mortality. Also, urging the consideration of each district medical society regarding the importance of the prevention and early diagnosis of cancer, and of tuberculosis. Many of the societies are considering these subjects.

The work of the Committee on Public Health Education Among Women, of the American Medical Association, was referred by that Association to each state as part of the work of the state medical society. The Committee on Public Health has therefore ap-

pointed Dr. Abbie Noyes Little of Newburyport to conduct a campaign along these lines. Dr. Little co-operated with the Department of Public Health of the Woman's Municipal League of Boston in arranging a course of five health lectures during February and March. These were held at the League rooms and were successful.

At the request of the Committee on Philanthropies of the Massachusetts Federation of Churches, members of the Public Health Committee of the Massachusetts Medical Society met with them to see if some method of coöperation might be devised whereby the doctors and ministers throughout the state might coöperate for the benefit of their local communities.

It was voted: That it is the sense of the meeting: 1. That more intimate and practical coöperation should be established and maintained between the Massachusetts Federation of Churches and the Massachusetts Medical Society, for the purpose of improving the health of this commonwealth.

2. That the churches of every community (through their local federation where one exists) should consult and coöperate with its physicians in matters of public health.

3. That the fundamental need is that of a competent health officer in every city, township or group of towns.

4. That whatever specific local needs in the line of health are discovered, should be taken up, both educationally and practically, by coöperation of the churches and the physicians.

Following the meeting, addresses by a member of the Committee have been made at three Social Institutes arranged by the Federation of Churches. One was at Springfield, one at Littleton and one at Middleboro. In all three the emphasis of the talk was upon the need of especially trained, full-time health officers in all cities and towns throughout the commonwealth. It is expected that this method will reach many people outside of the medical profession, rousing interest in various problems having for their object the improvement of the sanitary and social conditions of the people.

The Chairman of the Committee was a delegate to the Conference of the American Medical Association on Public Health and Instruction (including medical legislation) at Chicago, Feb. 15 and 16. Also the Chairman made an address on "Courses and Degrees in Public Health" at this Conference, the proceedings of which have been published in full in the *Journal of the American Medical Association* and are not detailed herewith.

The Committee regrets the resignation of its valued member, Dr. Mark W. Richardson. Having been Chairman since the beginning of its work, he was particularly fitted to meet the various questions arising from time to time.

Respectfully submitted,

M. J. ROSENAU, Chairman.

Dr. Lincoln Davis reported for the Committee on Hospital Efficiency as follows:

At the Annual Meeting of the Council in 1914, the President was empowered to appoint a Committee on Hospital Efficiency, to consist of five members with instructions as follows:

1. To make a report at the annual meeting of the Council in 1915, as to the present state of medical and surgical efficiency of the hospitals of Massachusetts, as far as can be determined from the annual reports of these institutions.

2. To obtain from the superintendent of each institution, a statement as to which individual or departments are held responsible for a high standard of results in the medical and surgical treatment of their cases.

3. To obtain from each individual or department an answer to this question: "Will you adopt some simple form of morbidity report for in-patients, if the majority of hospitals of the state agree on a uniform plan?"

Your Committee has endeavored to comply with these instructions, and begs leave to submit the following report:

In answer to the first instruction, we find that the annual reports of the Massachusetts hospitals, so far as we have been able to get at them, are with very few exceptions made upon the same general plan; a plan which conveys little definite information for the determination of the value or efficiency of the work done by the medical or surgical staffs. There is no uniform system of classification, so that comparisons are quite impossible, and an accurate knowledge of what is meant to be included under the different headings, is exceedingly difficult to obtain. Some idea of the relative frequency of different diseases and injuries in a given community, and the immediate hospital mortality, are all that can be gained from the best of the hospital reports, as at present prepared.

In answer to the second instruction, out of 146 letters of inquiry, 52 hospitals were not heard from at all; 17 did not specifically answer the question asked. Of those who replied, four said the responsibility rests with the superintendent; four, that it rests with a committee of the trustees; 14, with an executive committee; 17, with one member of the staff or chief of staff; and nine, with the medical and surgical staff. In nine cases it was said that each individual was responsible for his own cases, and in 20, that the responsibility was not fixed.

The character of the replies would lead your Committee to believe that in most instances the responsibility is purely nominal.

In answer to the third instruction, your Committee finds a very surprising and gratifying unanimity of sentiment in favor of a uniform system of morbidity reports, each institution, very properly, of course, reserving its final decision until some definite plan is submitted, but practically all expressing sympathy with the idea, and a willingness to coöperate in any plan that is practical and not too expensive or burdensome.

Having thus complied, as far as possible, with the instructions of the Council, your Committee would venture to suggest that in its opinion there are three important ways whereby the medical and surgical efficiency of the hospitals of the state may be increased.

First, by definitely fixing the responsibility for the results of hospital treatment.

Of the different plans for securing a direct personal responsibility, the Committee believes the most efficient and the best, is the establishment of a continuous service or services, with a chief or chiefs, who shall render an account of service to the board of trustees to be published as a part of the annual report.

Second, by the establishment of a follow-up system, whereby the end results of treatment may be learned and reviewed, and if practicable, published.

Third, by the adoption of a uniform classification of diseases, and form of morbidity report.

We beg leave, therefore, to submit the following recommendation:

That the appointment of a Committee be authorized by the Council, to consist of representatives of the medical and surgical and administrative departments of the hospitals of the state, to further consider the means of increasing their medical and surgical efficiency along the lines suggested, and to prepare a plan of uniform hospital report, which, upon the approval of the Council, should be recommended to the favorable consideration of the hospitals of Massachusetts.

Respectfully submitted,

HOMER GAGE, Chairman.

P. P. JOHNSON

P. E. TRUESDALE

J. T. BOTTOMLEY

LINCOLN DAVIS, Secretary.

Voted, To accept the report and adopt its recommendation.

The president reappointed the same committee to carry out the recommendation of the report.

Dr. W. P. Bowers presented the subjoined motion, explaining that it was not the purpose to interfere with any committee of the Society, but on the contrary, to assist by providing an executive officer, the rights of the Society being, in his opinion, safeguarded:

Moved, That a committee consisting of the President, the Secretary, the Treasurer, the Chairman of the Committee on Membership and Finance, and the Chairman of the Committee on Public Health, be and hereby is elected with full power to confer with Mr. Henry Copley Greene, Dr. Arthur B. Emmons, 2d, Mr. Carl Carstens, and Miss Mary Beard, or any of them, and when deemed advisable may accept and disburse such funds as may be donated to the Society by or through the above mentioned Greene, Emmons, Carstens, and Beard, or any other persons, for the purpose of hiring an agent who shall, under the direction of this Committee of the Massachusetts Medical Society, assist in the dissemination of information, and in the carrying on of any function of the Society, in public health work, legislation, social service, or similar departments of effort.

Dr. Dolan was opposed to the motion, for he thought it would not bring about a proper solution of the midwife question. On being put to a vote the motion was carried.

Dr. Gay spoke of the valuable services rendered by Fellows of the Society in the defence of malpractice suits against members and introduced the following motion which was passed unanimously:

Moved, That the thanks of the Council of the Massachusetts Medical Society be, and they hereby are, extended to the following Fellows for their unselfish and efficient services as experts in defending suits for malpractice in the courts against Fellows of this Society: Drs. G. B. Shattuck, F. S. Newell, F. J. Cotton, J. B. Blake, G. W. W. Brewster, H. A. Lothrop, A. W. George, C. J. White, W. J. Dodd, F. S. Burns, of Boston, Drs. E. H. Stevens of Cambridge, C. E. Prior of Malden, and H. W. VanAllen of Springfield.

REPORT OF THE LIBRARIAN.

The Librarian reports that during the past year he has attended to the various duties of his office, sending the publications to Fellows who have paid for preceding years and reporting payments to the publishers of the BOSTON MEDICAL AND SURGICAL JOURNAL so that the JOURNAL may be promptly received.

A directory of the Officers and Fellows was compiled and issued as a supplement to the JOURNAL. It is hoped that the Fellows will report at once any change of address in order that the Directory for 1916 will be as accurate as possible.

Respectfully submitted.

EDWIN H. BRIGHAM, Librarian.

Voted, to accept the report.

Dr. C. M. Green introduced this amendment to the by-laws on behalf of the Committee on Membership and Finance and action on it was deferred until the October meeting of the Council:

The Committee on Membership and Finance respectfully recommends the following change in the by-laws, to wit, in Chapter VII, Section 3, that the word "June" in the last line of the fourth paragraph be changed to "March," so that the clause shall read:

"This dividend shall be apportioned among the district societies according to the number of annual assessments which shall have been paid to the district treasurers previous to March first."

Dr. C. J. Allen referred to the activity of the *Journal of the Association of Retail Druggists* in advancing a propaganda restricting the dispensing of all drugs and remedies to pharmacists, and offered the following motion:

Moved, That the chair appoint a committee of three who shall investigate the advisability of employing legal aid in safeguarding the interests of the Society in matters that may come before the Massachusetts Legislature. They shall ascertain the approximate cost of such aid and report with recommendations to the next meeting of the Council.

On being put to a vote the motion was carried by a vote of 63 in favor and 23 opposed. Thereupon the president appointed this committee: C. J. Allen, G. W. Gay, C. M. Green.

The Nominating Committee brought in this list of officers and on proceeding to ballot they were declared elected:

President, Charles F. Withington, Boston; Vice-President, Edmond F. Cody, New Bedford; Secretary, Walter L. Burrage, Boston; Treasurer, Edward M. Buckingham, Boston; Librarian, Edwin H. Brigham, Brookline; Orator, David L. Edsall, Boston.

On nomination by the president the following Standing Committees were appointed for the ensuing year:

Of Arrangements.—J. D. Barney, E. L. Young, Jr., J. H. Young, J. L. Huntington, R. H. Miller, C. H. Lawrence, Jr.

On Publications and Scientific Papers.—G. B. Shattuck, E. W. Taylor, R. B. Osgood, J. S. Stone, F. T. Lord.

On Membership and Finance.—C. M. Green, A. Coolidge, Jr., Samuel Crowell, F. W. Taylor, Alfred Worcester.

On Ethics and Discipline.—J. A. Gage, J. W. Bartol, Henry Jackson, G. deN. Hough, S. B. Woodward.

On Medical Education and Medical Diplomas.—H. C. Ernst, C. F. Painter, H. W. Newhall, J. F. Burnham, C. Frothingham, Jr.

On State and National Legislation.—C. F. Withington, F. G. Wheatley, G. W. Gay, A. K. Stone, W. P. Bowers.

On Public Health.—M. J. Rosenau, W. I. Clark, Annie L. Hamilton, E. H. Bigelow, R. I. Lee.

Adjourned at 1.26 p.m.

WALTER L. BURRAGE, Secretary.

Miscellany.**REGISTRATION OF PHYSICIANS IN MASSACHUSETTS.**

THE following is the complete text of the act recently passed by the Massachusetts General Court relative to the qualifications for registration of physicians in this state.

"Section 1. Section three of chapter seventy-six of the Revised Laws, as amended by chapter three hundred and forty-six of the acts of the year nineteen hundred and thirteen, is hereby further amended by striking out all after the word 'applicants,' in the third line, down to and including the word 'secretary,' in the eleventh line, and inserting in place thereof the words:—Applicants for registration under this act, who shall furnish the board with satisfactory proof that they are twenty-one years of age or over, and of good moral character, and that they have received the degree of doctor of medicine, or its equivalent, from a legally chartered medical school having the power to confer degrees in medicine, shall, upon the payment of a fee of twenty dollars, be examined, and if found qualified by four or more members, shall be registered as qualified physicians, and shall be entitled to certificates in testimony thereof signed by the chairman and secretary,—so as to read as follows:—Section 3. Applications for registration shall be made upon blanks to be furnished by the board, and shall be signed and sworn to by the applicants. Applicants for registration under this act, who shall furnish the board with satisfactory proof that they are twenty-one years of age or over, and of good moral character, and that they have received the degree of doctor of medicine, or its equivalent, from a legally chartered medical school having the power to confer degrees in medicine, shall, upon the payment of a fee of twenty dollars, be examined, and if found qualified by four or more members, shall be registered as qualified physicians, and shall be entitled to certificates in testimony thereof signed by the chairman and secretary. An applicant who fails to pass an examination satisfactory to the board, and is therefore refused registration, shall be entitled within one year after such refusal to a re-examination at a meeting of the board called for the examination of applicants, without the payment of an additional fee; but two such re-examinations shall exhaust his privilege under his original application. Said board, after hearing, may by unanimous vote revoke any certificate issued by it and cancel the registration of any physician who has been convicted of a felony or of any crime in the practice of his profession. The board may subsequently, but not earlier than one year thereafter, by a unanimous vote, reissue any certificate formerly issued by it or issue a new certificate, and register anew any physician whose certificate was revoked and whose registration was cancelled by the board. All fees re-

ceived by the board shall, once in each month, be paid by its secretary into the treasury of the Commonwealth.

"Section 2. This act shall take effect upon its passage. (Approved May 28, 1915.)

In conjunction with the above it is noted in the recent bulletin (No. 10) of the Massachusetts State Board of Insanity that that board has taken up with the board of registration in medicine the question of employing unregistered internes and physicians, there having been some query as to the legality of this procedure.

'The Board is able to report that all staff physicians must take an examination and register in July, or else they will be liable to prosecution for practicing without a license.

As to internes, we quote from a letter from the Board of Registration in Medicine under date of June 2, as follows:—

"Internes who are to all intents and purposes students would not be required to become registered, but if a man receives a salary which is paid because of his medical knowledge, and does exercise his medical knowledge, then he is practicing medicine as defined in the law and must be registered.

"This Board is not inclined to push this matter up to the point of splitting hairs, and is only dealing with the question when the evidence is clear.

"We are anxious to secure a conference of the hospital authorities and have the law amended so that there will be no harm done to any honorable person and that every person concerned can know exactly what is meant under the law."

With this end in view the Board of Insanity has asked the secretary of the Board of Registration in Medicine to meet in conference with the medical men of the state institutions under the State Board and discuss the whole matter.

Correspondence**PARIS LETTER.**

"SPRING AS USUAL,"—NOTWITHSTANDING THE WAR!

(From Our Special Correspondent.)

PARIS, May 31, 1915.

Mr. Editor: After a winter unaccustomedly protracted even for this part of the world, spring has at last suddenly unfolded its beauty to our eyes in a single burst. This resembles a little what is said to take place in the far North, where the growth is held back so late, and has to accomplish so much in such a very short period, that on a perfectly still night you can hear the buds opening and the new leaves unfolding their blades. The Scandinavian God, then, who could see at a hundred leagues, and hear the grass growing in the fields and the wool on the sheep's back, was not so entirely a creature of fancy as might be imagined. We under this degree of latitude have to endure much in the way of winter gloom, the chilly dampness; but I must confess that I am sometimes almost prepared to admit that it is worth

while going through all of this, to be finally rewarded by such a sight as the beauty of Paris in early May. In fact, from the look of the Avenue in the morning hours, with its luxuriant vegetation and new wood pavement, the men leisurely cutting the lawns, the thousands of prettily-dressed children with their nurses, and the cavaliers and ladies passing to and from the Bois, no one would dream we were in the midst of the most deadly war ever waged; the only strange note in this Spring-harmony is the deep musical whirr of the aeroplane sentinel as he patrols back and forth high up above our heads with his vast wings glistening in the sun.

It would, I think, be difficult to find in any large city such lovely prospects, in their fresh green of spring, as the Parc Monceau, the reach from the Luxembourg to the Observatoire, the Avenue du Bois, and the island in the big lake in the Bois de Boulogne; these stretches were laid out by a consummate artist, the variety and coloration of the trees on the island being in particular something quite extraordinary. I once knew some people who lived high up above the horse-chestnuts on the Avenue de l'Observatoire; I never saw a more charming sight than to look down in spring on those undulating treetops covered with red or white conical inflorescences and watch them gently dip and rise before the puffs of wind, exactly like the waves of the sea. I wonder whether any of you have had the good fortune to notice the wondrous spectacle that surrounds at this season the main *pièce d'eau* just back of the Luxembourg palace, where tier upon tier of lilacs, hawthorn and horse-chestnuts, in both their varieties of pink and white, are massed in a vast hemicycle? There are also certain drives in the Bois where after any violent shower the pink or white blossoms of the acacia or horse-chestnut are beaten down in such quantities as to form for a day or so a smooth, even, colored carpet beneath the trees.

Just outside of my bedroom window stands a solitary acacia in the neighboring garden, a tree that has come sadly down in the world, one of the few stragglers survivors of the woods that once covered this western slope of the hill now crowned by the Arc de Triomphe. Promptly at the first suspicion of dawn, earliest of all his congeners, a blackbird perches himself on the topmost bough, and during a brief period pours forth amid the uncanny stillness his exquisitely liquid notes. The blackbird is in this part of the world the uncontested leader among the feathered songsters, and whether at the break of day, or after sunset, his deliciously pure modulations are a never-ending delight. I should not venture, even in my wildest flights, to attempt to reproduce either in writing or in music his marvellous cadences, interspersed at intervals with derisive shrieks; others have done so, however, and I beg to submit to all lovers of this dainty bird the latest effort in this direction. A Norse writer thus describes for his compatriots the song of the blackbird:

Huitja.

huitja, huitja, tret, tret, tret tsivil,
tsivil, tsivil, ha, ha, ha!

Let us pass on without comment. The man meant well, no doubt, and possibly that is the way the notes sounded to him. If certain people are color-blind, I see no reason why others should not be tone-deaf. Or perhaps, now that horses and dogs talk and do arithmetic, that particular bird was trying to sing in the vernacular of Norway. Certainly no blackbird I ever heard made such sounds as that; and what makes me think I am right is that there did once live a writer who had an ear, Aristophanes, who in his "Birds" has reproduced sounds that come uncommonly near to the notes of the blackbird:

tiō, tiō, tiō, tiotingx: to to to tingx:
iōi, iōi, iōi: torotix, torotix;
triotō, triotō, tobotoxix; iō, iō,
iō, iō, kinnaban, kinnaban, lililix!

Aristophanes' protagonist was, it is true, the hoopoe (tepos), a bird that is not a songster, but simply makes a noise similar to a whoop, whence its name. The hoopoe was introduced into the play only on account of its brilliant plumage, and of the comical scenic effects that could be drawn from its abnormally prominent and erectile crest. But among the chorus figure both the blackbird (kopsichos) and the nightingale (aedon), common birds in Greece, and with which the author must have been thoroughly familiar; so that it appears unquestionable that the above sound-mimicry was an attempt on his part to reproduce the song of these two latter birds which has much similarity. All of this question of the reduction to letters of abstract tones is very personal and based on acuteness of hearing and on musical training; but certainly, so far as I am concerned, Aristophanes' effort would pass very closely for the blackbird, that *tiō* and *tingx* reproducing rather neatly the piercing final notes of so many of its periods. But at any rate, pray compare his imitation with our Norse friend's effort!

A French naturalist speaks of the blackbird "whistling an absolutely invariable cadence in a minor key, incessantly beautified by fresh variations,—this bird being an incorrigible plagiarist;" and he refers to a case where a blackbird and a nightingale had built nests in the same tree, the outcome being that the former learned to copy the latter so accurately that no one could distinguish between the two. This is another instance of the importance of the personal equation in the estimation of differences in sound;—thus, it would never have occurred to me to say that a blackbird "whistles," or that it always sings one and the same cadence in a minor key. And this reminds me of the tale of the travelers in Turkey who were asked to note down on paper as nearly as they could how the word *baksheesh* sounded to their ears, and of the curious results that ensued! When you come to think of the matter, the power to distinguish between sounds is in reality a question of training. If we were all to set to work to learn the blackbird's tongue, we should ultimately reduce it to symbols about which we should all agree; it is only because one of us occasionally takes a wild shot at the subject out of passing curiosity that the results are so divergent. Consider what happens with the telephone. If someone rings, and says in French to my French servant that M. Martin or M. Dupont wishes to see me, there is not the slightest trouble; but if an Englishman telephones that Mr. Jackson or Mr. Harrison is at the apparatus, he has often great difficulty in getting the name correctly. No doubt we personally should have equal trouble in catching even approximately a Russian or Spanish name.

The region of Paris simply swarms with blackbirds. Every old court that contains a tree or two, or merely a wall covered with deep, dark ivy, will harbor at least one pair; and when the young are hatched the parents can be seen all day long scurrying over the sod and hauling out and slaughtering the inoffensive earthworms that seem to constitute their food of predilection. In the Bois, at the time when the young are large enough to leave their nests and be taught how to make their way in the world, you will sometimes find in secluded parts flocks of twenty or thirty together,—rather a strange sight, with such very shy creatures as these. Paris is surrounded on every side with beautiful, well-watered forests, so why these timid birds, with such limitless possibilities at their choice, should elect to live in shut-in courts in town, is a conundrum,—particularly as their favorite earthworms are not so very plentiful in a paved city. This custom hardly seems to harmonize with what Chaucer says about a bird's disdain for cages and luxury:

"Yet hath this bird, by twenty thousand fold,
Lever in a forest, that is rude and cold,
Gon gte wormes and swich wretchednesse."

I have often wondered how it is that we have no nightingales in this part of the world, since they are on all sides of us, so to speak. I once spent a spring at Bellagio, on Lake Como, and the noise they made there at night was enough to preclude sleep. Andalusia, in southern Spain, is notorious for its nightingales. And all of that charming group of men that have written at such length about country life in England, Gilbert White, Charles Cornish, and Richard Jefferies, speak of the nightingales in spring in terms that fill one with consuming envy. In some districts near London they are to be found in such abundance that they have given their name to the place; thus, in a side-glen of the Surrey hills, running down to the deep stream of the Wey, south of the Thames, there is a Nightingale Valley, while north of the same river, in the Brent Valley, not far from Ealing (in reality a part of Greater London), there is a preserved wood of twenty acres that is famous for these birds. Here again we find the facts in opposition to Chaucer's lines,—think of birds that could nest on the shores of Lake Como or in Grenada among the glades of the Alhambra, coming to rear their young in the dingy suburbs of London!

It has now been so long since I really had a chance to listen to the nightingale's song that I should not attempt to say what it is like; nor does the reproduction of its notes seem to be an easy task, from all I hear. No less a person than Verdi had a try, it appears, but abandoned the attempt; yet no one would venture to question the degree of cultivation of his sense of sound. The authority on this matter is naturally a Herr Professor, Beckstein by name, though even he admits that he has succeeded only very approximately. The following is (as nearly as I can translate his remarks, some of his terms being unfamiliar to me) what he has to say on the subject: "The nightingale's song is composed of twenty-four cadences clearly distinguished by their first and last notes, and comprises about 185 trills and flourishes: it is a succession of melodies interspersed with organ-points and beautified by coloration." That is the best I can do with it,—understand if you can; but it all sounds very German.

Our ancestors did not possess the words "Spring" and "Autumn," but used in their stead "Lenten" and "Haerfest;" thus, there is a mediæval poem which runs:

"Lenten ys come with love to tounne,
With blosmen and with briddes rounne."

All of these delightful old Anglo-Saxon words have now been practically discarded, having gone down before the progress of the Latin element of our language. Harvest-time has now a limited meaning, as also Lent; while blossom has become flower, and as for "to rounn," how many of my readers are there who have any idea what it means! Lenten is from the verb meaning to lengthen; the word therefore indicates the time of year when the days grow longer. But although words may differ, the season itself remains the same, and at each renewal thereof we only find ourselves more and more deeply conscious of its wondrous beauty, its healthy joys and endless promises. I think, however, that at no time has the awful horror of the present war affected me so strongly as at present. The idea that, at this season of the songs of birds, of the luxuriance of blossoms, and of the renewal of life, the men who ought to be on the farms hard at work at the labors of peace, tending the lambs, planting their gardens, and tilling the fields, are crouching by the million in the endless trenches that stretch from one end of Europe to the other, trying to exterminate each other by every device that the science and ingenuity of man has been able to create,—is one that is simply appalling. If in the hereafter there be a tribunal for the apportioning of reward and punishment, the people that precipitated this, the greatest calamity of all history, have indeed a fearful reckoning in prospect.

APPOINTMENTS.

BOSTON CITY HOSPITAL. In the pathological department Dr. George S. Graham has been appointed second assistant pathologist, and Dr. Edgar M. Medlar, research assistant in pathology.

RECENT DEATHS.

DR. J. WALTER BEAN, who died on June 20 at West Medford, Mass., was born in Sutton, N. H., on June 7, 1855. After studying medicine with Dr. M. M. Russell of Concord, N. H., he received the degree of M.D. from the University of Vermont in 1882. After practicing his profession for three years at Lyme, N. H., he pursued post-graduate studies in New York and in 1890 settled at West Medford. He was a member of the American Medical Association, of the New Hampshire State Medical Society and president of the Medford Medical Society. He is survived by his widow and by one son, also a physician.

DR. JAMES EDWIN CLEAVES, who died at his home in Medford, June 20, 1915, was born July 5, 1853, in Somerville. He was a graduate of the Harvard Medical School in the class of 1879 and had been a councillor of the Massachusetts Medical Society for several years. Formerly Dr. Cleaves was a member of the Medford board of health. He is survived by his widow and by one son, also a physician.

DR. GUSTAVUS F. WALKER, who died in Boston on June 1, was born at Hodgdon, Maine, in 1843. At the outbreak of the Civil War he enlisted in the Twentieth Maine Regiment, with which he served throughout the war. Subsequently he studied medicine at the Boston University and at the Vermont Medical College, and since 1888 had practised his profession in Boston. He was a member of the Boston District Eclectic Medical Society. He is survived by his widow, one daughter and one son, the latter being also a physician.

DR. PENELOPE DRINKIN WEISS, who died on June 24 at Gedney Farms near White Plains, N. Y., was born at Watertown, Mass., the son of a physician, in 1843. He had resided for many years in New York City and was dean of the New York College of Dentistry.

THE USE OF MAGNETISM FOR LOCALIZING NEEDLES IN THE TISSUES; WITH THE REPORT OF CASES.*

BY GEORGE H. MONKS, M.D., BOSTON.

A SHORT time ago I published in the JOURNAL a preliminary report on the experimental use of magnetism for locating needles in the tissues.† Some days thereafter my attention was called for the first time to a few articles in certain ophthalmological journals, in which essentially the same method that I have employed was advocated for the purpose of determining the position of bits of steel or iron within the eye. On perusing these articles I met with references to others, and it soon became clear to me that the method which I have suggested is not new, even in general surgery, as I supposed it was when I presented my first communication on the subject.

It appears that in 1880 Thomas R. Pooley² published an article on the detection of steel and iron bodies in the eye by means of a magnetic needle. Asmus¹² in 1894, elaborating the idea, devised a very delicate apparatus, which he called a "sideroscope," an instrument which a few years later was modified by Hirschberg.¹⁴ In the same year in which the description of the apparatus of Asmus was published, Gallenmarts¹⁵

demonstrated a "magnetometer" devised by Gerard for the same purpose.

The use of these instruments, which has apparently always been very limited, has now, I understand, been largely done away with since the introduction of the Roentgen rays. Although the instruments themselves are very ingenious and are capable of great precision, they are also very delicate and are easily affected by outside influences, electrical, magnetic, etc. They also require an expert to run them. I am told that it is very doubtful whether they have in ophthalmological work any single advantage over the Roentgen rays, except, possibly, in the saving of time.

The first person of all, however, so far as I can discover, to use magnetism for the purpose of localizing steel or iron bodies in any part of the body, was Smee,¹ whose article appeared in 1844; and to him, therefore, apparently belongs the priority in connection with this procedure. Since his time a few other articles on the use of this method in general surgery have been published by different writers, but no great improvement on Smee's original suggestions has apparently been offered.

Smee recommended that the foreign body buried in the tissues should first be magnetized; and for this purpose he suggested "transmitting a galvanic current, at right angles, to the suspected part," or magnetizing the object by induction, using an electro-magnet, and he recommended that the magnet be held as close as possible to the supposed foreign body for about half an hour. For an indicator he used a sewing needle suspended by a silk thread. He also

* The methods herein described were demonstrated, and some of the cases were reported, at a meeting of the Boston Surgical Society, March 1, 1915. See JOURNAL, p. 639.

† The JOURNAL, Vol. clxxij, No. 8, Feb. 25, 1915, p. 283.

used a needle, about six inches long, mounted on a steel point. He referred to a case in which he was able to detect "a piece of needle impacted in the finger of a young woman."

Aveling² recommended the use of the magnetized needle suspended by a silk thread, but he did not speak of the necessity of first magnetizing the buried needle. He referred to two cases where apparently this mode of detection was used with success.

J. H. Pooley³ conducted a number of experiments, and as a result made the statement that in the magnetic test properly applied "we have a certain and available means of diagnosing the presence of needles buried in the flesh, even when imbedded at considerable depth." He thought the method deserved to be more thoroughly known and appreciated.

Th. Kocher⁴ related the case of a woman who consulted him on account of pain in the thenar eminence of the right thumb. The presence of a foreign body in the tissues was thought possible, although no definite history was available. An incision had already been made by another doctor, but no foreign body had been found. As the pain persisted, the median nerve was exposed through an incision near the elbow, and then stretched but the pain continued. A neurologist, whom the patient finally consulted, expressed the opinion that her symptoms were due to the presence of a foreign body, and recommended another operation. The attempt was made by means of a large electro-magnet to draw the foreign body to a place where it might be definitely localized by the sensations of the patient, or by palpation, but without success. The foreign body was, however, finally localized by a delicate galvanometer, and was at once removed through an incision. Kocher, referring to the "Vorzügliche Diagnose" of the neurologist, says that the evidence furnished by the use of the galvanometer was so striking that, after he had witnessed the demonstration, he not only was certain as to the presence of a needle in the tissues, but was sure that he would be able to find it. Apparently neither Kocher, nor those who subsequently wrote upon this subject, were aware of the early articles of Smee, Aveling and others.

Dumont⁵ reported the case of a washerwoman who forced a needle into the thenar eminence of the right hand, about half of it remaining in the tissues. After several unsuccessful attempts to find the needle through incisions, it was finally localized by the use of an electro-magnet and an astatic needle,* and was then removed.

Kälin⁷ published the details of a number of experiments made by him on the magnetic attraction exercised by needles, knife-blades, bits of steel, etc. In the process of magnetizing these objects, magnets of various kinds were used, while a galvanometer, or astatic needles were employed as indicators.

Graser⁸ had a case in which he was successful in locating a needle by magnetic means. He thought the method a good one, but considered that its use must be limited to places where a large electro-magnet is available, since without previous magnetization the test succeeds only when the foreign bodies are of very large size.

Kummer⁹ reports the case of a seamstress, in which the fragment of a sewing needle was removed from the right knee, after it had been magnetized by an electro-magnet, and localized by a mirror galvanometer.

Lauenstein¹⁰ relates a case in which the fragment of a needle lay imbedded in the palm of the hand for six weeks, and was then correctly localized by the use of a magnetic needle. The foreign body was found and removed.

Charon¹¹ gives the case of a boy of nine years, in whose knee-joint a needle fragment was accurately localized by means of the apparatus of Gerard (which apparatus apparently has a telephonic attachment). A galvanometer was used as a control.

The above articles vary greatly in their interest and value; while in some of them it was evident that the writers understood very little about the subject of magnetism, and that they had apparently made no effort to study it; in others a number of careful and systematic experiments on the subject were recorded. Little or no weight, however, was laid upon the fact that it is the ends of the buried needle (that is, the two poles) which attract or repel, and not the body as a whole—a statement which can easily be proved by using the suspended needle as an indicator, or even a compass.

CASES.

I take the liberty of reporting here a few cases in which I have endeavored to localize needle fragments in the tissues by means of magnetism; and, after reporting these cases, I shall try to state definitely, of what practical use, if any, such a method may be at the present time, especially now that we have the x-rays. The cases herewith reported were referred to me by my colleagues at the Boston City Hospital, and I take this occasion to acknowledge their kindness. All the localizations were done by me, and also all the operations, except in case No. 5, and in one other.

CASE 1. (Referred by Dr. J. Bapst Blake.) Sarah B., 40 years old, was washing clothes on the evening of Feb. 16, when a needle entered her right hand, point first. The needle broke, and about half of it remained in the tissues. The next day she went to the City Hospital, where an x-ray photograph was taken. The plate having been examined to determine the approximate position of the needle-fragment, and also its axis, a horse-shoe magnet (kindly given to me by Dr. R. A. Coffin) was applied in such manner as to bring the long axis of the buried needle as nearly as possible into the line between the two poles of the magnet, as

* "A magnetic needle whose directive property has been neutralized." Century Dictionary.

shown in Fig. 1. The magnet was held in that position for a few moments only. This figure also illustrates the well-known fact that, when a steel or iron body is magnetized by one pole of a magnet, the end of the body which is nearest that pole acquires a polarity opposite to that of the adjacent pole of the magnet; that is, the end of a body nearest to the N pole of a magnet becomes the S pole of the body, and the end of the body nearest the S pole of the magnet becomes the N pole of the body.

FIG. 1.

Diagram indicating the general location of the needle, and showing the method of applying the horse-shoe magnet so as to bring the long axis of the needle into the line between the two poles of the magnet.

A magnetized steel needle, about half an inch long, suspended by a fine silk thread, was then passed over this region, close to the skin, when the attraction and repulsion of the two poles of this needle showed with accuracy where the two ends of the buried needle lay. The N pole of the indicator needle was attracted to the S pole of the buried one, and the S pole of the indicator needle to the N pole of the buried one. (See Fig. 2). On the other hand, either pole of the indicator needle was repelled by the similar pole of the buried needle.

Under ether, an incision was made in the long axis of the buried needle, and, finally, the indicator being used from time to time, the fragment was found at the bottom of the wound and removed. It was found best, at the time that the indicator was being used, to retract the lips of the wound by means of sutures, as metallic forceps or retractors attracted the indicator needle and interfered with the search. The needle fragment removed measured 7/16 of an inch (11 mm.) in length.

CASE 2. (Referred by Dr. Walter C. Howe.) Frances W., 51 years old. Needle penetrated foot on Feb. 20, while patient was walking across floor "in stocking-feet." She went immediately to the hospital, where an attempt was made to remove the needle, but without success.

On Feb. 24, an x-ray plate having been furnished (Fig. 3), the buried needle was magnetized by one pole of the magnet, and that end of the needle

FIG. 2.

Diagrams showing fragments of needles (buried in the tissues), and indicator needles suspended by silk threads (outside the skin). The buried needles have been magnetized, so that the S pole of each happens to be nearest to the skin.

The N pole of each indicator needle is being attracted to the S pole of the buried one, and the S pole of each indicator needle is being attracted to the N pole of the buried one.

In the first two diagrams the skin surface is horizontal, in the third one it is inclined at an angle.

which was nearest the skin readily located even before the stitches were removed. Ether was given, the wound was opened, and the needle was readily found and removed. It measured about 5/8 of an inch (15 mm.) in length.

FIG. 3.

Sketch made from the x-ray plate, showing, from one point of view, the position of the needle in the foot. The dotted lines indicate two of the different positions in which the magnet was held: one pole (in this case N) of the magnet being kept as near as possible to the nearest part of the buried needle, and the other (S) being brought as near as the shape of the foot would allow to the other end of the buried needle.

CASE 3. (Referred by Dr. Howe.) Majorie J., 14 years old. Fragment of needle in tip of left index finger. Although a Roentgen plate was furnished, it was hardly necessary to have one, since a dark spot in the skin indicated the exact position of the needle-fragment. The fragment was very minute, and the indicator was only feebly attracted to it. It was removed without difficulty.

CASE 4. (Referred by Dr. Horace Binney.) Wini-fred F., 24 years old. On March 2, while the patient was using a sewing-machine (run by power) the machine needle entered the terminal phalanx of the little finger of the left hand, and then broke off. It was not certain that the needle fragment

was still in the finger, but, as a careful search failed to bring it to light, this was thought to be possible; and, therefore, the next day the patient went to the hospital where an x-ray plate was made. Before the plate was developed, however, the needle was magnetized along its supposed track in the finger, (see Fig. 4), after which the indicator showed, without the slightest question, that the foreign body was in the place where it was thought to be. Under novocaine anesthesia, it was readily removed. One interesting feature about the test was that the indicator was attracted far more strongly on one side of the finger than on the other side, thus proving without doubt that the buried fragment was nearer the surface on the one side than on the other—an inference which was changed to a certainty when the x-ray plate was brought. The incision was of course made on that side, and the needle was readily found and removed. It was 5/16 of an inch (8 mm.) in length.

FIG. 4.

Showing diagrammatically the position and direction of the needle fragment in the tip of the little finger of the left hand. The horseshoe magnet is in such a position that the line between its two poles corresponds with the long axis of the needle-fragment. The dotted lines show the position of the magnet when it was moved so as to bring the other pole of the magnet near the other end of the needle.

CASE 5. (Case of Dr. Binney.) Lillie M., 24 years old. While she was wiping off a table a needle ran into the fleshy part of the right hand at the base of the thumb. On the next day, March 24, she went to the hospital, where the needle was magnetized, and localized before the Roentgen plate, which had previously been made, was brought to the clinic. The needle was readily found, and removed by Dr. Binney. It was 7/8 of an inch (22 mm.) in length.

Besides these five cases, there have been a few others in which I have tried magnetic localization. In some of them the test was fairly successful, while in others it failed entirely. In two of the cases (from the Oral Surgery Clinic at the Harvard Dental School) the fine hollow needles of novocaine syringes had been broken off in the soft tissues inside the mouth; in the one case on the inside of the ascending ramus of the jaw, and in the other in the gum close to the periosteum covering the alveolar process.

In both cases the breath of the patient prevented the indicator needle from being at rest, but a small compass introduced into the mouth gave rough information as to the general position of the needles, both of which were found and removed. In the case of a boy, (referred by Dr. F. B. Lund) in which a small needle fragment, according to the x-ray plate, lay deeply imbedded beneath the ligamentum patellae, the test failed entirely, probably on account of the depth at which the needle lay. It was only moderately successful in the case of a man (referred by Dr. J. C. Hubbard) in whose hand lay a piece of steel from the head of a cold chisel. The piece was about 1/4 inch long and 1 1/4 inch wide, and lay at considerable depth from the skin surface. It is quite possible that in this case the steel fragment was not sufficiently hard to retain a full charge of magnetism. That it did receive a certain amount of magnetism, however, was proved by the fact that, after it had been removed, it attracted the indicator needle in a very noticeable degree whenever the needle was brought near to it.

MAGNETIZING THE BURIED NEEDLE.

In my experience it is absolutely necessary in some way to magnetize the buried needle, for unless this is done, a magnetic indicator is not affected in any way until the indicator is so close to the needle as almost to touch it. For magnetizing the needles in all the cases here reported I have used either electro-magnets or ordinary steel magnets. Without much question a needle fragment may be charged with magnetism more strongly by an electro-magnet than by the ordinary steel one; and also it is probable that within certain limits the more powerful the electro-magnet the more powerful the charge will be, and the greater the distance through which it can be transmitted to the needle fragment. When, therefore, an electro-magnet is available it should perhaps be used in preference to an ordinary steel magnet; but for ordinary purposes a large horse-shoe magnet, especially on account of its low cost* and the ease and simplicity of its use seems to answer most requirements. The method of using this magnet is illustrated in Fig. 1, in which the importance of holding the magnet, if possible, in such a manner that the long axis of the needle shall lie in the line between the two poles of the magnet is emphasized. Under such circumstances the buried needle becomes magnetized instantaneously, but the charge it receives is apparently somewhat increased by bringing each pole of the magnet successively as close to the adjacent pole of the needle as possible, and by repeating the action several times (See Fig. 4).

USING THE INDICATOR.

For an indicator I have generally used a very fine magnetized needle suspended by a delicate

* Such a magnet may be bought at the Holtzer-Cabot factory in Brookline for sixty cents.

silk thread, or even by a human hair. I have also used a very small compass, as well as various other contrivances made of steel, and of different shapes and sizes. Generally the indicator, having been sterilized by immersion in 70% alcohol, was moved slowly over the supposed site of the buried needle. If the indicator were a suspended needle, it was allowed to swing freely in the air. In using such a needle one should not forget that its natural tendency is to lie in a line from the N. to the S., and that, when swinging free, it is also very subject to outside influences, such as draughts, electric currents, etc. I have at times found it best to make a separate test with each pole of the indicator, and for this purpose I have first drawn the needle through the knot in the silk thread in such a manner as to enable one pole to hang lower than the other, and then, after carrying this pole slowly over the skin surface of the affected region, I have done the same thing with the other pole. The test will, I think, be found more delicate when carried out in this manner than when the indicator needle is horizontal and both poles are on the same level. Once or twice a test was made with the magnetic needle suspended within a vacuum in a test-tube. I have not used a galvanometer or even astatic needles. Such instruments may perhaps be of use in cases in which the foreign body cannot be found by simpler means.

THE OPERATION.

If the needle is superficial, and its position is pretty definite, local anesthesia will be sufficient; on the other hand, if it be deeply placed, general anesthesia will probably be more satisfactory. As a bloodless condition of the part is of prime importance a tourniquet should be used, if possible.

If the axis of the needle lies more or less parallel with the skin surface an incision which is at right angles to an axis of the needle is probably the proper one from a purely operative point of view;* and yet, as the ends of the needle will not be exposed in such a wound, an incision of this kind, if the operator wishes to employ the magnetic test from time to time during the progress of the operation, does not seem to be ideal. In case the magnetic test, combined or not with the x-ray plate, shows one or both ends of the needle to be within easy reach, it would seem best to make the incision so as to expose one of these ends or the other. This incision might still be made at right angles to the needle, and yet be near to one of its ends. A second incision might be made to join the first one, if necessary, making a V, or a T, or even a crucial, incision. Through such incisions the magnetic test could be applied from time to time.

* Graser was apparently the first to emphasize this, for he recommended making an incision "in querer Richtung gegen die angenommene Lage des Fremdkörpers."

For retraction of the edges of the wound, during the test, instruments made of steel or iron should not be used. Satisfactory retraction may be secured by means of ligatures passed through the lips of the wound, or by the use of aluminum strips, or some other simple method.

When a part of the needle has been exposed in the wound one should be very careful in all manipulations lest the foreign body be again lost to view. This is one of the situations where a steady hand and a delicate touch are especially desirable.

CONCLUSIONS.

Although the brilliant and satisfactory results obtained through the use of the Roentgen rays apparently seem to have rendered unnecessary all other methods of localization, I cannot help feeling that in *certain cases*, even in those in which a Roentgen plate has been furnished, the magnetic test, if properly conducted, may be of distinct assistance to the surgeon. This test will probably be most successful in the following cases:—

1. Cases in which the needle fragment is large enough to receive and to retain a charge of magnetism sufficient to attract the indicator needle.
2. Cases in which the needle fragment is near enough to the skin to be strongly magnetized, and also near enough to attract the indicator needle.
3. Cases in which, during the progress of an operation, the incision opens up the tissues in such a manner that the indicator needle may be brought very close to the foreign body.

In all other cases, especially in those in which the needle fragment is very fine or very small, and also those in which it is far from the skin, the test is of doubtful value. Finally, I would say that all these remarks refer only to cases where the foreign body is a needle, or a needle fragment, and they do not refer to cases where ordinary fragments of steel or iron are imbedded in the tissues. I have not yet had sufficient experience with such cases as to enable me to generalize.

As already stated, a powerful electro-magnet is to be preferred for purposes of *magnetizing the buried needle*; but, as such an apparatus is not often available, a large steel horse-shoe magnet will probably answer all requirements.

Though a galvanometer is presumably the most sensitive *indicator* as to the position of the buried needle, nevertheless, for practical purposes, a very small compass, or a piece of fine sewing-needle suspended by a delicate silk thread will probably be found sufficiently sensitive.

Unless other considerations contraindicate, the *incision* had best be made in such manner as to open up the tissues near one, or both, ends of the buried needle. Of course no instruments

of steel or iron should be near, when the test is being applied.

I wish to thank Prof. D. T. Cumstock of the Massachusetts Institute of Technology for a number of valuable suggestions concerning the use of magnetism for the above purposes.

POLLEN THERAPY IN HAY FEVER.*

By J. L. GOODALE, M.D., BOSTON.

WITHIN a few years numerous reports have appeared in regard to the treatment of hay fever patients by the subcutaneous injection of pollen extracts. The writers, among whom may be mentioned Freeman, Noon, Cook, Clowes, Koesle, Manning, Oppenheimer and Gottlieb, have uniformly reported that a certain number of patients so treated have received more or less complete relief from the disease.

The object of the following paper is to report the results of observation based upon 123 cases of hay fever examined during the past 12 months with reference to determining if possible the value of this treatment, and also to ascertain what biological relations, if any, exist between the pollen of different plants.

In the first place, a word should be said in regard to the method of obtaining and preserving the pollen extracts. For many plants, which furnish an abundance of easily detached pollen, it is sufficient to gather the partly opened flowers, bring them into a room without currents of air, and in the course of a few days, the pollen may be shaken upon smooth paper. This applies particularly to those plants the cross fertilization of which is effected through the agency of air currents, such as many forest trees and grasses, and certain *Compositae*, particularly ragweed. In the entomophilous plants, where the cross fertilization is largely effected by the agency of insects, the freshly opened anthers may be clipped and gathered. The pollen is then either placed in the solution for extraction, or it may be preserved dry for an in-

definite period. I have taken pollen from specimens in my herbarium gathered 25 to 30 years ago, of grasses and of ragweed, which on the addition of water excites as marked a skin reaction as would be the case with freshly prepared extract.

The extract is obtained from the pollen by soaking in water for a few hours. I have not found it necessary to subject the material to trituration, as advised by some writers, and this is also theoretically unnecessary since the pollen grains in water promptly undergo a swelling, with solution of their albuminous contents. Several observers have complained of the difficulty of preserving the extract, and say that it is liable to deterioration on standing. After a number of tests, an alcohol dilution of 13 to 15% by volume seems to meet the requirements, and material prepared in this way a year ago has apparently lost little of its efficiency. It is interesting to observe in this connection that we have an example of a natural plant juice, namely wine, in which preservation of its qualities is thus secured. The heavier natural wines contain a considerable amount of albuminous matter, together with approximately 14% alcohol. More than this percentage checks the further development of the yeast plant, and this amount, while preventing decomposition, does not seem sufficient to cause a precipitation of the proteids of the wine.

It is desirable to keep the solution in amber bottles.

A word of caution should be said in regard to the gathering of flower heads for the preparation of pollen extract in the case of those plants which may contain a poisonous substance, as occurs in certain *Compositae*, especially the wormwood group. I have observed a few cases where disturbing symptoms of nausea and malaise followed the injection of such material to a greater extent than would be accounted for by the actual amount of pollen present. In the case, however, of such plants as the *Rosaceae* and grasses, these precautions are unnecessary and we may in the case of the latter, find it more convenient to strip off the flower heads or anthers by hand.

When the pollen has been gathered, and a suitable extract obtained, the latter constitutes then the stock solution from which varying dilutions are prepared. It is theoretically desirable to prepare the stock-solution with a definite percentage of pollen-extract, but with present laboratory methods this is difficult, and, moreover, it is not absolutely essential, since individuals differ very widely in their degrees of sensitization, and each case must be examined by different dilutions, to determine the correct strength which it is safe to use for the patient.

As has been described by other writers, and by a previous publication of mine, the tests are made by making a series of superficial scratches on the skin of the arm, and gently rubbing in a drop of the pollen extract to be tested into a scratch. After five to 15 minutes the positive re-

* Read before the American Laryngological Association, June 2, 1915, at Niagara Falls, Canada.

actions are indicated by varying degrees of local disturbance. These disturbances of the skin may be ranged in order of intensity as follows: In some cases the first perceptible alteration consists in a sharply circumscribed white area, not elevated, bordering the scratch for a distance of $\frac{1}{16}$ to $\frac{1}{8}$ of an inch. We may find in other individuals the first manifestation to consist of a slightly reddened raised area. In more pronounced disturbances the area of swelling is more extensive, and is more or less white in color, being surrounded by an area of reddening of varying size. When this degree of disturbance appears, it is usually accompanied by itching. It may, in marked cases, attain a considerable size, the edematous area reaching one inch or more in diameter and surrounded by half an inch or more of hyperemia.

The intensity of the skin reaction does not always seem to be proportionate to the clinical symptoms of hay fever. I have seen numerous severe cases where the skin reaction was much less than in other individuals who apparently suffered from a milder form of the disease. In the case of children the skin disturbances are relatively less pronounced than in the case of adults, and I have observed several under ten years of age, with apparently well-defined hay fever, who showed no reaction to the prevailing pollens borne in the air at the special season.

Examination of my cases by this method shows that the hay fever season in eastern North America may be divided into four periods as follows: The first period coincides with the flowering of the earliest blooming plants, the second with the flowering of the grasses, the third with the midseason flowers of July, and the fourth with the opening of the autumn blooming Compositae.

Of the first period 13 patients were observed who gave positive reactions to one or more of the following plants:

Coltsfoot (*Tussilago*)
 Dandelion (*Taraxacum*)
 White maple (*Acer dasycarpum*)
 Willow (*Salix nigra*)
 Alder (*Alnus incana*)
 Birch, white, yellow and black (*Betula papyrifera*, *lutea*, and *lenta*)
 Hawthorne (*Crataegus* sp.)
 Apple (*Pyrus malus* and *floribunda*)
 Lilac (*Syringa* var.)
 Oak (*Quercus rubra*)
 Tulip
 Lily of the Valley.

The symptoms which these early bloomers excite are relatively mild and depend chiefly upon the abundance of the plants in the vicinity of the patients. For many individuals the annoyance is so slight as to be perhaps not worth treating. In others a residence surrounded by maples or oaks, or with an orchard close at hand, may cause considerable discomfort. The most severe cases of this season which I have seen were

from maple and oak. If there is only one sensitization, the period of disturbance is brief and disappears with the drying or shedding of the flowers in question.

The second period represented by 36 cases, is ushered in with the flowering of the grasses. Owing to their abundance and the range of the blooming period of the different species, it is relatively severe and prolonged. Coincident with their flowering we may find an associated disturbance from many garden flowers, but for the majority of individuals, these latter are of minor importance. It is probable that if these June cases can be rendered immune to grasses, the other causes will be borne without much trouble.

The third period, represented by 10 cases, has been shown by my observations to be due in great measure to the mid-season Compositae, such as field daisy, hawkweed, yarrow, etc. With these are many species reported by patients which are still to be studied, such as chestnut, phlox, mountain laurel and numerous other plants of restricted distribution.

The fourth period with 77 cases begins with the general flowering of the ragweed, golden-rod, asters and the late Compositae and lasts until frost. My examination of the fields and roadsides at this season shows that the common plants other than the Compositae are relatively innocuous, and may be disregarded. Such are in the vicinity of Boston, the wild carrot (*Daucus carota*), pigweed (*Chenopodium*), hardhack (*Spirea tomentosa*) and other representatives of these families.

From the foregoing observations it is evident that in this vicinity the chief causes of hay fever are the grasses and late Compositae. The early and midseason forms are briefer and less severe.

The possibility has been suggested that sensitization to proteids may arise through some parenteral entrance of the albumen in question into the body, and that hay fever, for instance, may originate from the contact of a given pollen with a scratch or abrasion of the skin. If this should be the case, it would certainly lay the method of testing by skin reaction open to serious objection, as we should thereby run the risk of exposing the individual to numerous sensitizations. I have gone over this point carefully with many patients testing them repeatedly with pollens to which they were originally negative, and have not, in any case, discovered the subsequent development of a sensitization.

METHOD OF TREATMENT.

The pollen extract is injected subcutaneously, and not into the muscles, as pain or stiffness may follow in the latter case.

The dosage is determined in the following way: After the special exciting pollen has been ascertained by the skin test, a second series of scratches is made at a distance from the first, and different dilutions of the pollen extract in

question are applied. It is important not to have this test applied in the vicinity of the skin which has been reddened by the first tests, as an increased excitability of this region is present, and even a simple scratch will cause localized swelling. The dilutions may be most conveniently made by adding a certain amount of the stock solution to alcohol of the same strength, and a 25%, 10%, 1%, and even weaker dilution of the original extract are applied to the second series of scratches. The initial dose is determined by the dilution which fails to excite a definite skin reaction, and for the sake of causing as little smarting from the alcohol as possible, the quantity of material injected should not exceed five or ten drops. I should also recommend postponing the injection of even a small amount until after the reaction from the first skin tests have subsided, since a considerable amount of absorption from these probably takes place, and the introduction of an additional amount has seemed to me in a few cases to cause systemic disturbance. The injections may be made at intervals of two days to a week, increasing by a few drops at first, and later by the adoption of stronger percentages of the stock solution. To avoid the risk of anaphylactic disturbance, I have advanced the strength at first slowly. After five or more injections have been given, the strength may be increased with greater rapidity. The disturbances occasioned by the injection of the pollen extract below the skin consist, when a sufficient strength has been attained, of a more or less well-defined lump, varying from the size of a bean to that of a pigeon's egg, accompanied by a sensation of moderate heat and itching. It is interesting to note that none of the patients have complained of these manifestations as representing more than a trivial degree of discomfort, and in no case has the disturbance been sufficient to cause the patient to interrupt treatment.

Two instances of distinct but harmless anaphylactic shock were observed, one occurring in August in a man who came in somewhat exhausted from the heat, who showed extremely marked skin reactions, and who received on the same occasion a small dose of ragweed pollen extract. About half an hour after the administration of the pollen extract, he was taken with faintness, nausea and vomiting, and had to be assisted home. The other case was that of a boy who received a dose of grass and dandelion pollen insufficient to cause local skin reaction, but who, a few hours later, was taken with moderate prostration, nausea and vomiting. It has seemed to me consequently a wise precaution to make the initial dose approximately one-tenth of what the patient can theoretically receive with safety. After a number of injections have been given, it is practicable and safe to inject a strength which may cause distinct skin reaction, without exciting general disturbance.

Beyond the immediate anaphylactic shocks

above noted, I have seen in a few cases where ragweed pollen has been injected occasionally a more or less marked persistent general depression. Since using the pure pollen extract, such a condition has not occurred in my own practice, but it has been reported to me by patients treated by other physicians. It seems to me here to be a question whether there has been an injection of toxic material other than the pollen, or whether the dosage has been excessive.

RESULTS OF TREATMENT.

We have two methods of determining the effects that have been accomplished by the injection of pollen extracts, first, the behavior of the skin reactions; second, the patient's observations regarding his condition. The first phenomenon being objective in character should afford a more reliable guide as to what has been accomplished.

INFLUENCE OF TREATMENT UPON THE SKIN REACTIONS.

In those cases which it was possible to observe for a period of two weeks to several months, the skin reactions were carefully noted at regular intervals. Of these, 62 showed a distinct diminution in the size and intensity of the disturbances in the skin, two showed no appreciable change.

The time required for the diminution of the skin reaction varies within wide limits, dependent both upon the plant tested, and upon the individual himself. In the case of alder, willow and apple, I have sometimes obtained a marked reaction from the first application, but on repeating the application two days later, a diminution or total disappearance was noted. This sudden disappearance following the first scratch was noted also in a case of horse fever, which showed on one afternoon a very extensive swelling from the application of antitoxine to a scratch, but who on the following morning, tested with the same antitoxine, showed no reaction, and has shown none since. In the case of grasses, and even more in the case of ragweed, a slower disappearance of the reaction was noted. With ragweed and *Cosmos* particularly I have observed in some cases a persistence of the skin reaction, even after weekly injections carried on for a period of four to six months. In these more obstinate cases an increased tolerance, however, was noted in spite of the persistent swelling. This tolerance was shown by the disappearance of itching which the first injection had caused, and by the smaller amount of hyperemia surrounding the oedema.

Twenty-one cases of those whose reactions had diminished in the course of treatment were examined again after the lapse of two to six months. Of these 19 showed no return of the skin sensitiveness, and some of them showed a still further diminution. Three cases after the lapse of three months showed a distinct return toward their original degree of sensitization.

INFLUENCE OF TREATMENT UPON HAY FEVER SYMPTOMS.

In describing the results which have followed the injection of pollen extracts, it has seemed to me desirable to separate those cases which have received treatment during the hay fever season from those which have been treated during the winter or out of season. I have done this for the reason that it is difficult during the course of an attack to draw accurate deductions from the statements of the patients themselves. We have in the first place to remember that seasons vary in the severity of hay fever symptoms, dependent upon the amount of rain, heat and cold. Furthermore, the individual's predisposition seems to vary, perhaps as the result of his physical state and habits at the season. Finally the element of suggestion may conceivably play a part. While I shall therefore report the summer cases with reference to the degree of relief obtained, I do not regard these figures as at all conclusive. On the other hand, observations carried out during the winter with references to changes in the intensity of the skin reaction may be considered a fairly reliable guide, if it be admitted that the strength of the solutions themselves has not undergone deterioration. This latter point is difficult to determine with absolute certainty. Nevertheless, my alcoholic solutions seem now, after a lapse of months, to effect in new cases nearly, if not quite, the same degree of skin reaction, which they occasioned in a fresh state.

At the date of writing, 123 cases have been observed, of which 74 have had more or less treatment, 49 have been seen but once, or are now beginning treatment. Of the cases which may have been considered to have had a sufficient amount of treatment to enable us to draw more or less definite conclusions, 32 were treated after the onset of the hay fever symptoms, and 47 were treated during the winter or early spring. Of those cases which were treated at the beginning of the hay fever season, 26 expressed themselves as having been more or less relieved, eight could not see material improvement. In estimating the results actually achieved by treatment during the season I believe that an accurate judgment would place the extent of the relief in a number of instances distinctly below that which the patients expressed. It is possible that the element of suggestion plays here a considerable part.

Furthermore, a certain number of these who believed themselves improved showed but slight diminution in the extent of the skin reaction. It has seemed to me that such cases probably represent too high a degree of sensitization to obtain material relief during the hay fever season, and that a longer period of treatment is required. On the other hand, several of these individuals who reported several months later, showed a marked diminution in their skin reaction, and it was possible then to undertake their treat-

ment, with the result of bringing about still further a diminution in the intensity of the skin disturbances. About one-fourth, however, of those treated during the season experienced after a certain number of injections, ranging from four to 12 in number, such striking diminution in their subjective sensations and in the skin reactions that it seemed difficult to ascribe the gain to anything else than the treatment, the improvement noted having occurred from one to three weeks before the disappearance of their type of hay fever in this vicinity.

THE BIOLOGICAL RELATION BETWEEN DIFFERENT PLANT PROTEIDS OR POLLENS.

It is evident that in this work a knowledge of the biological relationships of the exciting plants would be of the greatest aid. If, for instance, we can say that the protein of two exciting plants is identical we shall need to inject the pollen of only one.

While we do not know clinically the relation of the different plant pollens, yet from a botanical standpoint, they have been studied by serological methods by a number of observers.

The methods employed were the precipitation reaction and the agglutination method. Extracts of the plant albumen were made, removing first, where present, fats, oils, acids, alkaloids, starches, glycogens and sugar. Those extracts were then injected into rabbits, preferably into the abdominal skin. As a rule the interval between injections was from three to four days.¹

With reference to the time required for immunization of the rabbits, no exact figures can be given. Sometimes a potent immune serum can be produced after three or four injections, but cases also occur where even after ten injections very little immunity had appeared—at times entirely failed to occur. Apparently the individuality of the animal is a factor. Uhlenhuth mentions that of ten rabbits injected with the same albumen, only one showed a potent immune serum. The test is done by removing a small amount of blood from the marginal vein of the rabbit's ear, adding a portion of the extract which was used for injection and centrifuging. If the serum is of high potency, a precipitate is shown. The animal is then separated from the others, not fed for 24 hours and then killed. The blood is received in sterile glasses from a carotid incision. The serum must be perfectly clear, and show no opalescence. Finally the serum must have no free antigen, that is, the animal must not be killed too early after the last injection. The serum, if absolutely sterile, is easily preserved in dark glasses and closed with sterile cotton.

Precipitation Method: Dilutions of the plant extract are made, beginning with 1 to 200 and ending with 1 to 50,000. To each of these dilutions

¹ Physiologische-systematische Untersuchungen über die Verwandtschaften der Angiospermen. Mez und Gähle, Cohn's Beiträge zur Biologie der Pflanzen, 1913.

a cubic centimeter of serum is given. After keeping in the thermostat for an hour at 37° centigrade in the more dilute preparations there is a precipitate which demonstrates the value of the serum. The procedure in the case of material related to the original one is analogous. A precipitate shows a relationship, the absence of precipitate indicates that relations of identity with the original albumen are not present.

Agglutination Method: Here one places in different glasses the same dilution of the extract according to the content of albumen, for instance, 1 to 200, and to these glasses different degrees of immune serum are added, 8-100 of a centimeter, 2-100 of a centimeter, 1-100 of a centimeter and 5-1000. These mixtures are then sensitized for two hours in the thermostat, and after the lapse of this time, 4-10 of a c.c. of fresh, active ox serum is added, whereupon in the case of related albumen coagulation occurs. This method has shown itself particularly adapted, provided we have a specially potent immune serum. In any serum, the two methods should be employed before important results are accepted.

It is desirable in these tests to bring the solution to the same content of albumen.

A large number of families have been already studied with regard to their position in the system. It has been shown that the development of the angiosperms extends from the Selaginellaceae over the pines towards the magnolias, that the yews divide laterally from the pines, while the Gnetales form another lateral branch of the conifers, and then the trunk runs from the barberries toward the roses and ends with the myrtles. The magnolias and barberries belong to the common stem of the roses and crucifers. The trunk must take a branch below the Ranunculaceae of which the ends are the crucifers and the roses. In phylogenetic respect the barberries are older than the buttercups. Likewise the pea family is closely related to the roses. The trunk then proceeds from the roses to the Crassulaceae and Saxifragaceae family and ends with the evening primrose and myrtles. The mignonette and Capparidaceae lie between the barberries and mustard family. Since the albumen of the mignonette and Capparidaceae reacts like the albumen of the poppies, it is pos-

(After Mez and Goltz.)

sible that the branch of the stem between the magnolias and Capparidaceae takes place above the mignonettes. Poppies do not act reciprocally with the mustard. The mignonettes, however, stand close to the violets. The Teasle family, Dipsacaceae, which apparently resembles the Compositae, does not react with it, and we have here to do with an interesting case of convergence.

The accompanying diagram shows the mutual relationships of the families which have been studied by their serum reactions. Unfortunately the position of the grasses is not given in this diagram, as they belong to a separate trunk, namely the monocotyledons, but this fact renders it sufficiently evident that their albumen is wholly distinct from that of the dicotyledons. It has, however, been established that they are closely related in their reactions to the Liliaceae.

From the foregoing considerations it is evident that the families which chiefly concern us in this present connection, namely the Gramineae, the Compositae, the Rosaceae and certain families of trees, have no serobiological affinity with each other. Consequently an individual sensitized to one family alone would not react to the pollen of a distant group. Where two families are closely related as in the Rosaceae and Leguminosae, a positive reaction might be expected to both. The clinical evidence in this regard extends as yet only to the Gramineae and the Compositae. Clowes showed in 1913 that in individuals sensitized to both grasses and ragweed, immunization against the former conferred no immunity against the latter. Much consequently remains to be studied in this respect.

In the case of genera within a given family, a relationship of proteids has been shown to exist as already stated. We should therefore expect an individual suffering from ragweed sensitization to react positively also to goldenrod and to the other members of the Compositae. A case which reacts positively to beach grass would also react to June grass, red top, etc. A case reacting to roses would react to apples, cherries, Spirea, etc. We have, up to the present time, clinical confirmation of this view only in the case of grasses. Noon and Freeman showed that injection with one species of grass would also protect against other grasses studied. While they found the pollens identical, yet some grasses seemed to yield a more active extract than others, and in their later work used timothy grass by preference. My own study of the skin reactions in the case of grasses confirms this view, and, as I have previously reported, patients sensitized to one species react positively to others, although one may bloom in June and another *e. g.* beach grass, in August.

Sensitization to the Compositae represents for us in America the most important form of hay fever. This is sufficiently shown by the generally accepted opinion of the majority of sufferers, and is confirmed by my own statistics.

The question, however, has remained as yet unanswered whether among the Compositae themselves subdivisions exist of a serobiological nature. While we may admit a sufficiently definite affinity to cause positive precipitation or agglutination reactions among all its members, yet it is conceivable that the proteid of the Compositae may be still further differentiated in a manner corresponding to the different genera. Following the same hypothesis we may imagine an individual sensitized primarily to the golden rod proteid, who may show only in a relatively minor fashion sensitization to ragweed, with which he has perhaps never previously come in contact. He may consequently show marked reaction to the former and but slight reaction to the latter, yet in virtue of the underlying biological affinity of the two proteids immunization to the one may confer resistance also to the other.

During the year I have studied ten species of Compositae representing as many genera, in an effort to obtain light upon this subject. Two methods have been used, first the classification of patients with reference to their reactions or preponderance of intensity of their reactions to the pollen of these Compositae, second observation whether injection of one species of pollen would influence the skin reactions to other pollens.

1. Classification of Reactions.

A summary of the relative frequency of the various sensitizations is as follows:

Ragweed, 82 positive cases, 24 negative.
Golden Rod, 48 cases positive, 50 negative.
Cosmos, 28 cases positive, 25 negative.
Field Daisy, 28 cases positive, 37 negative.
Hawkweed, 20 cases positive, 39 negative.
Yarrow, 21 cases positive, 28 negative.
English Daisy, 16 cases positive, 19 negative.
Tansy, 11 cases positive, 20 negative.
Coltsfoot, 5 cases positive, 2 negative.
Dandelion, 6 cases positive, 1 negative.

The disparity between these figures immediately suggests the question whether the different test solutions contained proteids of different strength so that individuals with but slight sensitization did not react to certain weaker solutions, when they might have reacted to stronger ones. That this is not the case seems to be shown by the following table of 20 illustrative cases.

From this table it is evident that all manner of variations exist in the primary or preponderating sensitizations of individuals. I have been particularly struck by the difference in the grouping of reactions exhibited by patients coming to me from different localities. As yet sufficient data are not at hand to enable me to generalize in this respect, but experience so far has led me to expect a different display of reactions in a patient of my vicinity from that shown in a patient from western New York or from the middle West.

TABLE I.

CASES	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Ragweed	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Golden Rod	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Cosmos	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Field Daisy	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Hawthorn	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Yarrow	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
English Daisy	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Tansy	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Collinsfoot	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Camellia	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20

The intensity of the skin reactions is shown by the numerals:
0=Negative; 1=Slight; 2=Moderate; 3=Considerable; 4=Marked.

2. Influence of Treatment upon Reactions of Related Pollens.

The second method of determining the relations existing between the proteids in the related genera of the Compositae, has been by the following method. A patient who shows sensitization to, for instance, ragweed and goldenrod, is injected in the usual manner with ragweed pollen and observations are made at intervals with reference to the golden rod reaction. In some of these cases so studied it has been evident that with the diminution in the intensity of the ragweed reaction, there is a diminution likewise in the golden rod reaction, which, however, follows at some distance behind it, until the ragweed reaction has nearly or quite disappeared, when there is a sudden drop in the golden rod reaction. My observations in regard to this point are as yet incomplete and demand further study before they can be regarded as conclusive. There seems, however, here a promising field for study, and the method is suggested for the consideration of investigators who are entering upon this work.

If these observations are confirmed, they will serve to indicate that there are slight differences between related genera and yet a fundamental relationship.

From the theoretic point of view it would follow that while we may be able to accomplish immunization to all members of a given family by the injection of pollen from one, yet more rapid results may possibly be attained by em-

ploying a mixture of these pollens to which the individual shows preëminent sensitization.

The question may possibly be raised whether the parenteral administration of plant proteids may cause harmful alterations in the organs of the body. Longcope has shown that nephritis may be set up in animals by the subcutaneous injection of egg white. No examinations have been undertaken, so far as I know, on hay fever patients, as to whether the injection of pollen extract has been followed by the occurrence of albumen in the urine. I have made no examination of my hay fever patients in this regard. A case of horse asthma which I have reported elsewhere, received for a period of several months weekly subcutaneous injections of horse serum, in doses which finally reached the amount of five drops at each injection. The urine in this case was examined before and after treatment with negative results.

CONCLUSIONS.

Serobiological methods have shown the phylogenetic relationship of the different plant orders and families. The application of these discoveries to the treatment of hay fever by injection of plant proteids promises to assist in the selection of the specific material required for a given case.

Definite reactions are elicited in hay fever by the pollen of the exciting plants when brought into contact with an abrasion of the skin. The intensity of these skin manifestations may be sensibly diminished by the repeated parenteral administration of the proteids in question. Coincident with the diminution in the skin reactions, there seems to occur an increased tolerance of the exposed mucous membranes to the pollens of the plants employed. Pollen therapy in hay fever may be regarded at the present time as a promising method of treatment, but its value and the permanence of its results remain still to be definitely established.

LEPROSY AND ITS RELATION TO MASSACHUSETTS.*

BY JAMES A. HONELI, M.D., BOSTON.

LEPROSY is not of such importance as tuberculosis to Massachusetts, but, nevertheless, is a problem which confronts us and which needs consideration and action. It is a disease of which

* Read at a meeting of the Boston Medical Library in conjunction with the medical section of the Suffolk District Medical Society, on March 31, 1915.

the great majority have a considerable dread,—a dread not based on experience or knowledge. The very fact that Massachusetts has been considered foremost in many public health problems would seem to indicate a thoughtful government and an intelligent population. In the matter of leprosy, however, we have lagged behind and the claim that we isolate our cases cannot excuse us from our attitude toward lepers or our neglect of them as patients. It is my endeavor, therefore, to interest you briefly in the problem as it relates to Massachusetts.

Leprosy is first and foremost a communicable disease and in isolating cases occurring in this state we are doing what is right and proper. New York's attitude in allowing them at large is not justified. Where we have been in error is, in not regarding leprosy as sufficiently interesting and important to warrant the better care and the proper study of our charges. In making ourselves more familiar with leprosy we shall be able to diagnose the cases earlier and when Massachusetts provides us with better facilities for treating and caring for these patients, we shall be able to attempt to prolong life either by making the course of the disease less destructive and serious or by curing the disease.

A year ago a case of leprosy with marked symptoms and lesions of the disease was reported and sent to Penikese. This patient had been treated by private physicians and been through the more important hospitals for a period of three years and was finally diagnosed at the Massachusetts General Hospital. He had been treated for diseases varying from catarrh to syphilis. He had what may be termed catarrh, but no bacteriological examination had been made of the secretion nor of the lesions which may be confused with syphilis. I am not criticizing the inability of the average physician to diagnose leprosy, but I do wish to indicate the possibility of patients who suffer from leprosy going the rounds of the hospitals and only being diagnosed when in a more or less advanced stage; or, if they realize their trouble, of returning to their own country or to the next state where they are free to spread the disease.

The attempt to teach physicians what the earliest lesions and symptoms are, is not my province tonight. But if it were, I would advise any who are so inclined to visit Penikese where we can give so-called dispensary instruction. Barely half a dozen visitors see Penikese during the course of a year, and half of these are from other states.

Just what are the earliest symptoms and lesions of leprosy, authorities are not agreed upon nor are the descriptions of the stages and forms of the disease uniformly and clearly defined. And much less do we know what the channels of infection are. The clinical phases of the disease have not been studied as carefully as the laboratory and experimental side of it. We can, however, distinguish, with little difficulty, cer-

tain manifestations which are typical of leprosy. Fever with or without a macular eruption, epistaxis, rhinitis or coryza, catarrh or other nasal symptoms, enlarged glands, areas of anesthesia, itching usually of the extremities, often variously described as biting, twitching or burning, ill defined pains, etc., macular areas, small nodules on the face are all described as early symptoms and lesions. A careful bacteriological examination of nasal secretions, which can be induced by pot. iodide, is advocated by a number of investigators. This is claimed also to cause the appearance of a typical febrile eruption and nodules in the skin which are not apparent on cursory examination. X-ray of the extremities is also claimed as a means of diagnosis of early cases; the lime salt absorption and resulting rarefaction of the terminal phalanges is the picture shown. The Wassermann reaction is positive in the majority of cases. Gland puncture and bacteriological examination of the smears is perhaps as definite a means of diagnosis as is advocated. And Marchoux, Couvy, Kitasato, Leboeuf and Jovelly, and others claim that by this method they have demonstrated the bacilli in persons who have been in close and intimate contact with patients and who had shown no signs of the disease.

It is impossible to expect the very early diagnosis of cases of leprosy here in Massachusetts. That can only be achieved in a circumscribed area like Hawaii, an endemic centre, where the Government inspectors are trained observers and where all suspects are detained pending further symptoms and examination. What we term early cases here, are cases where the patient has small but visible lesions and where the bacilli are readily procured from the secretion of the nose and nodules; these cases are generally in a sufficiently advanced stage to be a source of danger to the public. The results cannot be reckoned until such cases increase either among our immigrants or among the people with whom such patients have resided. If this is a logical conclusion, then in time there is no doubt that endemic centers will form, due to the increased number of infecting but non-diagnosed cases. This is brought out all the more when we consider that practically all the cases sent to Penikese have been discovered mostly by chance at the hospitals and then only when their symptoms and lesions are pronounced and of several years' duration. The following statement from Brinckerhoff and Moore's paper on the examination of nasal secretions among non-lepers at Hawaii is of interest, "One conclusion can be drawn from our results," they say, "which is of some public health importance. It is evident that no considerable number of individuals in institutions in Hawaii have, as the sole evidence of the disease, lesions in the nose which are discharging lepra bacilli. On the other hand we are inclined to lay great emphasis upon the finding, among the patients of the Free Dispensary, of a case which had a consider-

able number of lepra bacilli in the nasal secretion. We regard this case as of particular importance, because she had come to the dispensary a number of times and had, therefore, been under the passing notice of a physician who was familiar with leprosy and always on the lookout for cases of this disease. We regard such a case as a most dangerous one from a public health standpoint, and feel that the labor of examining smears from fifty odd nasal secretions was well repaid by the discovery of this case."

It is asked whether cyclic epidemics have occurred in Asia, Africa, Europe and South America; whether these epidemics have occurred in virgin fields and also whether the present endemic centers, more particularly those of Asia and Africa, are centers where the disease is less virulent and whether a certain amount of immunity has been established. The important point in all this is the establishing of new endemic centers—the possible spread from these endemic centers to other states and the possible increase in virulence of the disease in fields where the environment is suitable for the rapid spread of the disease. In proof of the possibility let me state a few facts based on what has occurred elsewhere. New endemic centers have been established in South America, South Africa, Nigeria and New Caledonia. In 1865 in New Caledonia the disease was introduced and in 1888 there were 4000 cases. In the West Indies the disease has doubled in the last twenty years. Marehoux, reporting on the increase of leprosy in France—and from his report there are approximately 300 lepers in Paris alone—is of the opinion that there is no great reason why the disease should not again become the scourge it was six or seven hundred years ago. In South Africa the disease is becoming a serious menace. In less than twenty years 223 fresh cases of leprosy among Europeans have been reported, and the government, realizing that every year the danger is increasing ten fold, is attempting the complete segregation of all cases, even those occurring among the native tribes. An observer in South America states that the disease there is more virulent than in other countries, that the period of incubation is shorter and that the disease is spreading rapidly. Although the Mexican government in 1910 sent circulars out to determine what means should be adopted to combat the scourge, nothing apparently has been done and Mexico has a very large number of cases. In parts of India and Europe this is also true. Hawaii is frequently quoted to bear out this statement. Leprosy was probably unknown there previous to 1848. In 40 years close to 5,000 cases were reported; the disease has reached its maximum incidence and hopes are entertained that leprosy will eventually disappear. In New Brunswick from 1815 to 1891 about 250 cases were reported and at present there are approximately 15 cases. The disease frequently decreases in one place and increases in another; there are apparent cyclic periods where the dis-

ease reaches its maximum incidence and then diminishes.

What are the facts regarding leprosy in the United States? Our imperfect system of registration and statistics prevents us from graphically or truthfully presenting tables showing figures that are of much importance. Leprosy is specifically reportable in 18 states. It is endemic in Louisiana and probably in Florida and California. A case occurring in Massachusetts in an American was undoubtedly contracted in Louisiana but under what conditions we do not know. In 1911 Rhode Island reported a case of leprosy in a school boy 15 years old. This case was diagnosed in Massachusetts. Another case which Montgomery reports was a man born in Massachusetts who had never left the country and who probably contracted the disease in the Chinese camp in Nevada. The South reported the first case, as far as accurate data are obtainable, in 1775. The disease must, however, have been known there and elsewhere in the United States previous to that. Massachusetts reported its first case one hundred years later. The United States Public Health Service reported 278 cases of leprosy in 1911 and of these only 72 were isolated and cared for by local authorities. Of this number 145 were born in the United States, 120 in foreign countries, and 13 were unknown. It was thought that 186 had contracted the disease here. But this by no means indicates the number of cases in this country. To show the fallacy of such reports, the next year, 1912, gave 146 as the number of lepers in the United States and showed leprosy to be in 17 states. Dyer in 1897 reported at the lepra conference that since 1800, 277 cases had occurred in Louisiana, and that in 1897, 113 cases were still on record. The following figures I have been able to procure regarding the number of lepers in the United States from personal communication with state authorities: In Louisiana there are 102 cases segregated, and on account of the lack of co-operation or lack of interest of physicians, full returns are not given. In the yearly report for 1914, received from their leper institution, this paragraph appears: "During those 20 years at no time has more than a comparatively small proportion of the lepers in Louisiana been confined in the institution." Of the 87 cases reported to be in the home the majority are males, but what is significant is that of this number 72 are white, and only 15 are colored. In California there are at present 33 cases cared for, Chinese and Mexicans are in the great majority, there being 12 Chinese and 10 Mexicans. Minnesota reports 11 cases, and of these several are Americans born in that state.—Leprosy among the Norwegians who originally settled there having practically disappeared. New York reported five new cases during the single year 1914, three of them in public hospitals, a child who was cared for at its home and one an alien who was deported. The Department of Health has made no provision for the supervision, quar-

antine or control of leprosy. I personally know of one case in Pittsburgh, Penn., one in Rhode Island and of course the fourteen here. This together totals nine cases more than was reported by the Government and includes complete figures from only four states and incomplete figures from two others.

In the Panama Canal Zone the authorities have had more than 100 cases since 1906, and approximately half that number are being cared for at present.

In Massachusetts we have had approximately 50 cases, and we receive an average of two to three cases a year. The great majority are of foreign birth, and thus far Chinese, Portuguese and Russian subjects have predominated. All told, ten nationalities have been represented. A great many of the cases have been deported. Several of the Chinese have been born in this country and three, at least, of the total number of cases were Americans. An English patient from Trinidad came to this country in the hope of a cure, and was finally sent to Penikese. Others have developed the disease from 10 to 14 years after their arrival. In 1882 White reported the presence of two lepers who had escaped from Tracadia, one of whom he had under treatment. In regard to the Chinese cases the question naturally arises whether the disease was contracted in the Chinese quarters of San Francisco or other cities on the Pacific coast, or whether on their visits to their own country. Montgomery in 1894, reporting on leprosy in San Francisco, thought it a possibility that several of the cases among the Chinese were contracted in San Francisco; he gives, among other cases, two that were here 20 and 16 years respectively before showing any signs of the disease. It is seldom, indeed, possible to obtain any information from patients a great many years after they have been here, as to when or under what conditions they have been in contact with cases of leprosy. We simply have to assume that a given case, coming twenty or more years ago to this country from a country where the disease is more prevalent, contracted the disease there and not here in the United States. Cases are on record where the disease has developed forty years after a residence in a country where the disease was prevalent. Bibb gives a case of a man 70 years of age who lived for 60 years among lepers, on the greatest social and most intimate terms, and then contracted the disease. Abraham quotes the case of a sailor 67 years old who had been retired in England forty years and had shown symptoms for the last six years only. Hallopeau relates the case of a man in whom the disease appeared 32 years after he had stayed in a leprosy country.

In 1905 Massachusetts began to segregate all cases of leprosy, considering it a communicable disease. Penikese Island was the spot selected for the isolation of our cases—an unfortunate selection on account of its situation, exposure

and barrenness. So far, some thirty cases have been cared for. In New York, as in many other states, the lepers are not segregated, and in New York leprosy is not considered communicable. This surprising point of view is incomprehensible. For this reason, if for no other, the Federal government should establish national leprosaria and provide for the proper care and treatment of all cases of leprosy. Massachusetts bases its conviction that leprosy should be segregated on the opinion of the best minds of Europe, America, Asia and Africa. At the last Leprosy Conference, held in Bergen in 1910, the following resolutions were adopted:

1. The Second International Scientific Conference on Leprosy confirms in every respect the resolutions adopted by the First International Conference of Berlin in 1897. Leprosy is a disease which is contagious from person to person, whatever may be the method by which this contagion is effected. Every country, in whatever latitude it is situated, is within the range of possible infection by leprosy, and may, therefore, usefully undertake to protect itself.

2. In view of the success obtained in Germany, Iceland, Norway and Sweden, it is desirable that other countries should isolate lepers.

3. It is desirable that the children of lepers should be separated from their parents as soon as possible, and that they should remain under observation.

4. An examination should be made from time to time of those having lived with lepers, by a doctor having special knowledge. It is desirable that lepers should not engage in certain trades or occupations. All leper vagabonds and beggars should be strictly isolated.

Among general conclusions reached at this conference the following is instructive: "Every leper is a danger to his surroundings, the danger varying with the nature and extent of his relation therewith and also with the sanitary conditions under which he lives. Although among the lower classes every leper is especially dangerous to his family and fellow workers, cases of leprosy frequently appear in the higher social circles."

In 1909 the Franco-Danish Commission for the study of leprosy made the following few conclusions:—

- a. The conditions under which the leprosy bacillus grows and develops are unknown.
- b. The channel of invasion of the human body is unknown.
- c. Leprosy is a contagious disease.
- d. Heredity in leprosy has not been proved.
- e. A positive cure for leprosy is not known.

There are certain difficulties in presenting the subject of the contagiousness of leprosy in this community. The fear of the disease is almost without parallel, and any presentation of proofs may have the danger of further increasing this fear. The opinion of the contagiousness of lep-

rosy is not based on the oft misquoted case of Father Damien at Hawaii. It would be unnecessary because a hundred better examples of direct contagion can be cited both in Americans and Europeans. But the opinion today is that leprosy is communicable only upon close and intimate contact with cases that are sufficiently advanced to discharge live virulent bacilli from fresh lesions, and this danger is enhanced when the skin or mucous surface is injured and direct inoculation takes place. Statements from British and Colonial delegates in 1910 were also significant: "The danger of infection from leprosy persons is greater where there is discharge from mucous membranes or from ulcerated surfaces."

Laws of resistance and immunity play probably as important a part in this disease as in others. Hansen, commenting on the Norwegian lepers that settled in the west and the gradual disappearance of the disease there, said that one of the first things immigrants learn in America is to keep their persons and their homes clean. In his opinion, cleanliness about the house and person is in most cases sufficient precaution to prevent the spread of leprosy. Since then this opinion has had to be modified. It is true that the disease is more prevalent among peoples who live in primitive and unhygienic conditions, but this by no means covers the whole problem. In hygienic centres the disease is practically absent; when the standards of living improve the disease tends to diminish. It should be said that the spread of the disease is brought about more readily by lack of hygienic conditions in addition to personal contact. Bayon suggests the following questions in seeking facts as to the contagiousness of leprosy: "The much greater incidence of leprosy in males than females. The universal spread of the disease under the most varied climatic conditions and the definitely greater proportion of infected children of leper mothers."

The action of Massachusetts in regard to segregation is abundantly justified. United States delegates to international conventions urged segregation, but so far without success. This occurrence of new endemic centres in the last fifty years should alone influence us. For what logical reasons should we believe that we are exempt from similar dangers? The disease undoubtedly has increased in the United States. In 1910 at the Bergen Conference, Ravogli, who attended the congress from America, made the statement that up to then (1910) no cases of leprosy had occurred among the soldiers who had returned after serving in the colonies, and he consequently did not think the contagiousness of leprosy was serious. Had Ravogli kept in mind the long incubation period of leprosy and the history of the disease in other countries he would have hesitated before making this statement. Several cases are given in literature of American sailors who had contracted the disease

outside the United States, and Hyde as early as 1878 gives a case contracted probably in Honolulu in 1863 or 1864. In looking over the Public Health Reports, for one year, from August, 1913, to June, 1914, I have been able to collect three cases among soldiers who had served in Cuba or in the Philippines.

I am not prophesying whether or not leprosy will increase in Massachusetts, but since much has been said of the dangers regarding the possible increase of tropical diseases here. I should like to add these four points for your consideration:—

1. Leprosy is exceedingly prevalent in Mexico, Brazil and Latin-America in general.
2. Boston is building up a South American trade and booming Boston as a port of entry.
3. The Panama Canal gives a more direct route to countries where the disease is endemic.
4. The unfamiliarity of our local authorities with leprosy.

I am, therefore, inclined to believe that Massachusetts is not free from the increase of leprosy. Russia believes that because she has acted as a sieve for the East in past generations, the disease is so prevalent there today. Germany claims she gets her cases from Russia, France from her colonies and her southern neighbors, Hawaii and other islands from China and Japan. In America we have a few states where the disease is prevalent, and a few others where the disease is endemic. What should the attitude of Massachusetts be, then?

First and foremost, a more tolerant and sensible attitude towards these unfortunates. A greater familiarity with the disease. A more sympathetic and true interest on the part of the state in their cases and a less complete isolation. To provide a modern hospital and modern buildings for the proper care and treatment of leprosy. In treatment much can be done, and reports of arrested cases are frequently made. The prevention of disfigurement, toxic febrile attacks, pain and general discomfort is successful in a great many cases. It is by no means so hopeless as was imagined some years ago. The closer clinical study of all cases reveals much that can be done for these people, but as far as our cases are concerned, very little more in the line of treatment can be attempted unless the state provides the institution with proper facilities. Dyer, in 1903, speaking from a sanitary standpoint, stated that "no institution pretending to care for lepers should be without the fullest equipment for bathing facilities. Water in leprosy is as potent in its prophylaxis as it is for remedial use." We have for two years studied the disease clinically and bacteriologically and we feel assured that there are many possibilities for treating our cases, but without equipment, without facilities to carry out our ideas, the work that has been done will prove to be without practical applicability. In the third place, the closer affiliation between university

and institution, so as to obtain the greatest good and stimulate interest in the problems which confront all state institutions is desirable, and lastly, federal control of immigration, which White recommended as early as 1894, with the establishment of at least two national leprosaria.

THE RELATION OF LEPROSY TO THE COMMUNITY.*

By GEORGE M. KATSAINOS, M.D., BOSTON.

ANYONE should hesitate, after hearing the splendid results of Dr. Honeij's research to touch the same subject before so well informed hearers. But since I had already expressed the desire to speak on the same subject, I will say a few words with the hope that a discussion from another point of view might help as to a better understanding of this very important problem. After all, leprosy is the most peculiar disease after syphilis. In examining the "relation of leprosy, or rather of the leper to the community," we must have three questions in mind: (1) Is leprosy a contagious disease? (2) What is the manner of its transmission? (3) Is it a curable disease?

In answering these questions we must take into account not only contemporary evidence, but also such evidence as we may gather from the past. The earliest reference to lepers seems to be the well-known passage of Leviticus, beginning with chapter thirteen, and following. It seems, however, that what is called leprosy in these chapters is a combination of psoriasis and vitiligo, and of other skin diseases. The purification and care of the leper and the leper's acceptance after the necessary purificatory sacrifice into the Jewish community seem to point to any other than the real and accepted disease that we call leprosy. We are also tempted to believe that the medieval world under the influence of ignorance and superstition which continued even after the times of Columbus, confused many other diseases with leprosy, and when syphilis invaded Europe it mistook it for leprosy, especially when mutilation resulted from syphilis, and they considered and treated syphilitics as lepers. Hieronymus Praecastorius, the first who gave the name of syphilis to the disease known until then as morbus Gallieus, in the well known poem, who is justly thought of as the "Homer" of syphilis, as late as 1530 refers to leprosy along with syphilis, mistaking evidently syphilitic ulcerations for "hideous or horrible leprosy." This confusion renders evidence coming from the distant past suspicious. It would be best, therefore, for our purposes to limit our premises to facts lying near our own observations.

Since I happen to be a Greek, born in a coun-

try which unfortunately has not yet been able to get rid of this terrible disease and where sufferers of this kind are numbered in many hundreds, I might justly base my discussion on facts that I have observed there.

As I said, lepers were always to be found in Greece. But within one generation after the War of Independence in 1821, the disease took such an alarming development throughout the country and especially in Peloponnese, that there was near almost every city and village, a segregated district for lepers, where all sufferers, without distinction of sex, age, or rank, were isolated by force. According to my belief this spread was due to the invasion of the Egyptian army which, under Ibrahim Pasha, landed in Peloponnese in 1825, and for almost four years wrought great destruction from end to end of that country, transmitting at the same time the seed of this disease, which is one of the greatest pests of Egypt. My native village of Lagadia, in the centre of Peloponnese in the mountainous district of Gortynia, had before the revolution a population of about 1500. After the passing of the Egyptian this number was reduced to one-third. Before the invasion there was not one case of leprosy, but after it a large part of this pitilessly decimated population was infected. The village is situated on a mountain side and is surrounded with running brooks and steep rocks, into which many caves are hollowed. These caves during the fearful years of foreign yoke, served often as places of refuge for people fleeing the tyrant's bayonet and torch. These caves were almost filled with lepers soon after the invasion. What is true of my village is also true of most of the cities and villages of Peloponnese.

Nowadays there is not a single case of leprosy in my village, although the population has reached ten times the number of the inhabitants left after the revolution. Throughout the province, with the exception of the village Valtesiniko, where sporadic cases are still to be found, the evil has been exterminated. In all Peloponnese one seldom meets a leper, except in districts along the seashore.

But although in Continental Greece the disease is reduced to insignificance, on the islands it is met not infrequently. According to statistics made by Dr. G. Ptoleimos, professor of dermatology at the University of Athens, and director of the Hospital (for skin and venereal diseases) of Andreas Sygros, on all the islands there are more than one thousand lepers. In the lepers' asylum in Spinalonga of Crete there are 230 patients; in another asylum on the island of Cyprus there are 250.

But the cloaca of Greek leprotic filth is Athens, a city filled with sufferers of this kind. Since persons infected with this disease are driven out from every village or city in Greece, abandoned by relatives and friends, and excluded by all communities, they mostly find

* Presented at a meeting of the Boston Medical Library in conjunction with the medical section of the Suffolk District Medical Society, on March 31, 1915.

their way to Athens, some seeking cure and others working to earn their living. There, these victims of a most hideous disease, find at last a place where they are not persecuted, and there they live their hopeless lives among the other inhabitants, either begging, selling shoestrings, and such trifles, playing hand-organs, or engaged in any other light work out of which they may earn some means to prolong their horrible days which they spend in neglect, filth, pain, contempt, and despair, wishing for an early death, and yet clinging to life desperately.

On the other hand, a leper in Athens who belongs to a prosperous family, or who by his own work can earn a large income does not feel the despair of the above-described outcasts. On the contrary, he takes his meals in the same restaurant and at the same table as any healthy person; not infrequently he drinks from a common glass; he constantly has his hair cut or shaves in the public barber shops; and he sometimes sleeps on the same bed with a healthy individual. Furthermore, his clothes are washed in the public laundry, or by a private laundress who makes no discrimination among her patrons. He rides in public carriages; he deals openly in the public market; he attends services in the same church with the rest of the people, and, on election day, he presses through the crowd or voters to cast his ballot.

In sharp contrast with the attitude of the Athenian public toward the lepers, is the inhuman way in which they are treated elsewhere in Greece. As soon as the disease manifests itself, and not only the doctors themselves but also the peasants become aware of its presence, the sufferer, whether willing or unwilling, must leave his village and home and must spend the rest of his life alone in some deserted place. His relatives, if he is fortunate to have such, or sympathizing passersby leave, always at a distance from the leper's hole, the necessary food, on which he barely lives. A kind of strange isolation, that results not from a written law, but from a commonly felt necessity due to custom, providence, and above all to social and religious tradition. The Mosaic law laid down in Leviticus is followed to the letter: "All the days wherein the plague shall be in him he shall be defiled; he is unclean; he shall dwell alone; without the camp shall his habitation be." Lev. 13:46.

I have known a shepherdess isolated on a desolate spot on one of the sides of a terrible ravine, in the midst of red oaks, prickly pawns, and ash trees. Her husband carried her food to her in weekly rations consisting of simple bread and of a small quantity of some other foodstuff. The poor woman died in her solitude and remained there, unburied for about a month until some people ventured to cover with a little earth what was left by the jackals and wolves which had devoured most of the miserable remains of the body.

Another man, a native of my village, who had

emigrated to Patzas, was attacked by the disease while there. He hastened to return to his home, but he had to spend the remaining two years of his life in a cave opening at the foot of a precipice near a spring of water, condemned and neglected by all except his sister, who, poor though she was, divided her food with him, carrying his part daily up to a distance of 200 metres from the cave.

Such heroes of woe could justly repeat the immortal Sophoclean words of the mythical King Philoctetes, who, abandoned for years on the island of Lemnos, speaks thus of his suffering to Neoptolemos (Soph. Phil. 530):—

"I believe that no one beside myself could not only suffer but even behold these agonies. But I have been foretaught by necessity to resign to pains."

Thus for two years the faithful sister shared her meals with her abandoned brother. One day, after bringing the daily food to the usual place, she greeted her brother across the ravine, but no answer came from the cave. Casting away all fear, she climbed up to the polluted hollow, and there she found her brother dead. Her pleas for a religious burial were unheeded by both clergymen and laymen. Despairing at the end she took axe and spade in her hand, and like the faithful Antigone of old, she buried alone her unfortunate brother. Such is the life and end of all lepers who cling to the vicinity of their homes as long as breath is left in them.

But the scientific Greek world hypnotized, one could say, by the theories and teachings of Zampacos, the well-known great student of leprosy in the East, does no more believe in the contagiousness of the disease. They accept it as a congenital and hereditary disease, even as the most hereditary of diseases after syphilis. To this rule I make an exception, I believe, with my fellow countrymen that leprosy is inherited, and that the microbe exists in the spermatozoa and ova in the time of the conception. On the other hand, I do not deny that contagiousness is also possible, for otherwise I could not explain the existence and development of the disease in certain times and places. Nevertheless transmission by contagion is only a rare exception, taking place in a way that escapes our detection. It is certain that it can result only from a protracted intercourse, combined with many other conditions, such as time, place, and, above all, predisposition of the organism for the admission, cultivation and development of Hansen's microbe. As proofs against opponents of the hereditary theory, I shall lay before you some of the cases which seem to admit no doubt.

The brother of my grandfather on my mother's side, John Mpakrisioris, marries the daughter of a leper. The brother of his wife also is a leper, but her mother is in perfect health. Eight years after the marriage Mpakrisioris' wife, too, shows the same symptoms. She is segregated with the other lepers and dies, leaving behind

her husband and three children, two boys and one girl. The father marries again soon after the death of his first wife, and from his second marriage three other girls are born and brought up together with the two boys and one girl of his first marriage. They sleep on the same bed with the other children, they use the same domestic utensils, they are taken care of by the same mother. The two boys of the first marriage at their twelfth year emigrate to Patras to earn their living. Twenty whole years after their emigration, they become lepers and die from the disease. The third child, too, of the first marriage is a leper at the twelfth year, is isolated and dies in a few years. Even after the manifestation of the disease, one of her playmates, a girl cousin of hers, who was to be my mother, continued to steal to the cave of her lost companion day or night, and play with her, eat with her, and sleep with her for some time. Mpakrisioris and his second wife die in old age utterly unmolested by the disease that thrived about them. All the girls of the second marriage lived free from the contagion.

There is another relative of mine who marries a girl of a leper family. A child is born. The mother soon is a leper. After her death the husband marries again, and five more children are born, who live in constant contact with the child of the first marriage. This child twenty-five years after the death of his mother, is attacked by the disease that had taken away his mother. But the father, the second wife and all the children from the second marriage remained unmolested.

Charalambos Mariupoulos has three children from his first marriage. When his first wife dies he marries again, a woman of leprotic descent, who bears no children but lives with her husband and the three children of the first marriage for many years. At last, seven years after her marriage, she dies from leprosy, whereas her husband and the children remain entirely unmolested.

Andreas Kapsis, father of three children and a neighbor of mine, succumbs to the disease when about forty years of age, leaving behind three children, two boys and one girl. The boys had left their home ten whole years before the manifestation of the first symptoms in their father. About fifteen years after their father's death, they, too, become lepers and as such return home. The mother, disregarding all danger, prefers to be isolated with her boys and to take care of them to the moment of their death. Yet neither she nor her daughter was affected and they both live at the present day in good health. The mother is about ninety now.

The brother of this Andreas Kapsis dies, likewise a leper, and leaves six children. Of those children only two had died from this disease; the other four and the mother have remained pure.

Tracing Andreas Kapsis and his brother to their origin, we find they are the children of a

leper and that thus their family tree has its roots in the disease sown by the seed of the Arabian invaders who had come to Peloponnese at the time of the revolution. Most of the members of this family die either of leprosy or of tuberculosis. Even the present generation, in spite of the mixture resulting from intermarriage with Greeks, shows most clearly the racial characteristics of their Arabian ancestors, from whom they have had this terrible disease as their only inheritance. All four children of one member of this family die of consumption. The only child of his brother succumbs to the same disease, the father himself dying of anaesthetic leprosy. The two children of the third brother die likewise of consumption. The same disease carries away the fourth brother.

What I have said about this family is also true of three other families of the same village whose members thus fall from Seylla to Charybdis, dying either from leprosy or by consumption. Are we to accept that leprosy prepares the ground for consumptive tendencies? At least these examples tend to confirm such a theory.

The cases that I have in hand corroborating my statements would much exceed the limits of time. From all these, however, the following facts are observed:—

1. No case of transmission of leprosy from the husband to the wife or from the wife to the husband is found.
2. No case of contagion between neighbors, however close their relations with a leper may have been.
3. No person related to a leper by any marriage ties, but not of the same blood, has been affected.
4. Even when a child is the suckling of a leper woman it remains unmolested, if not born of her.

After all, the Hebraic curse may have a scientific basis: "The leprosy therefore of Naaman shall cleave unto thee, and unto thy seed forever." II Kings 5.

But just as any field is not good for any kind of seed, so every country is not appropriate for the development of leprosy. Thus the United States, in spite of the fact that not a few lepers have found refuge in this country, refuses to yield ground to the disease.

It is well known that Norway is a most fertile field. Yet when Hansen himself came to the United States and made thorough investigations in all places where Norwegians have settled, tracing especially families sprung from a leprotic root, he found no victims here. (Crocker's Diseases of the Skin.)

Is not this a reason to believe that America is not a land favoring the development of leprosy?

It is also indisputable that places by the seashore are more suited for the spread and permanence of the disease than inland districts. Thus, to come back to Greece, although leprosy invaded

first the central part of Peloponnese as a truly Pharaonic plague in its most horrible form, and worked havoc for some time, its fading away has been equally rapid. Against all that we might expect from a curse of this kind, a disease not only chronic, but of a sudden appearance and seizing on so many victims at the same time in a place inhabited by a poor and above all, by an uneducated class of people, against all that we might expect from such a disease under such conditions, we find that within a period little longer than half a century the evil has been almost entirely exterminated.

In contrast with these fine results in inland places, we find that in spite of a more systematic and a more persistent prosecution, leprosy still thrives on the coast and on the islands, especially in Crete. And yet on this island a leper's home has been established since 1897 at Spinalonga and drastic measures are taken to segregate in this home every leper of the island as soon as the first symptoms of the disease appear. In Cyprus, too, after the English occupation (1878) another lepers' home has been established and severe measures have been taken against the evil. Yet there are 250 lepers in Cyprus and 230 in Crete.

These facts lead me to the conclusion that the proximity of sea water and fish food may be potent factors for the permanence of the disease.

Athens, on the other hand, is an inimical place to it; for, in spite of so many lepers who, driven out from every other part of Greece, find a refuge here and live undisturbed among other inhabitants, no case of contagion is reported, and no leper has been born.

With regard to the therapy of the disease, the best means afforded thus far is salvarsan, which I have seen extensively applied and which I have used often myself.

There is in Athens a very good hospital, named after its founder "Andreas Sygros," which has been established since 1905, and has since become a "pool of Siloam" for lepers, and is a unique institution in the whole world for the scientific study of leprosy. I had the good fortune to be connected with this hospital from August, 1913, to July, 1914, and to make a thorough observation of the splendid work conducted by Dr. George Photeinos, a young professor of dermatology at the University of Athens.

The lepers are not admitted as bed patients in this hospital, but they find here a place where they are well received, moulded, directed, and encouraged, and above all, where they are subjected to a splendid treatment without the least expense on their part, because the institution is well supported by the Greek government. Here one can see the disease in all its phases and stages, in sufferers of every sex and age, and within a period of six months can have a good idea of the disease itself, and of the method of treatment, as well as of the results of the salvarsan therapy.

But Dr. Photeinos has extended his sphere of action beyond this institution. In company with his assistants, Dr. Michaelides and Tsamaloucas, he went to Crete, in order to make a careful study of the various forms of the disease, supplied by the 230 patients of the Spinalonga lepers' asylum. He likewise provided himself with all things necessary for the Wassermann reaction, and applied this method in a temporary clinic established by himself. Combining all the material provided through these various sources, he has come to the following conclusions:—

1. In cases of tubercular leprosy the Wassermann reaction is positive on 76%.

2. In case of nervous leprosy its positiveness is 38%.

3. In case of mixed leprosy its positiveness is 75%.

4. This reaction seldom and with great difficulty changes from positive to negative, and this happens only after numerous injections—not less than 8—of salvarsan or of neosalvarsan. But since the patients do not return regularly to the hospital, exact statistics of the change and of the duration of negativeness cannot be given.

5. The curative action of salvarsan on lepers is not encouraging and is far from being considered radical. The nodules of tubercular leprosy often fade away, but to obtain such results 10-15 intravenous weekly injections of full doses of salvarsan are necessary.

The effects of the treatment in their best form I have had the opportunity to witness myself on a man coming from Cythera. He had come with tubercles as large as almonds covering his face, his back, his breast and abdomen, with a distinctly leprotic appearance. He was subjected to no other treatment except to ten intravenous injections of salvarsan. Last June, that is six months after the treatment, he came back with body cleared of every tubercle, in good condition and better spirits. No one looking on the face of this man could suspect that he was still a leper, a fact proved by discolorations of the skin of the breast and abdomen. These were sometimes as large as a silver dollar and always without sensation. The Wassermann reaction on him was still positive.

Most of the lepers treated, owing to their destitute condition and ignorance, do not persist in the treatment long enough to make the basis of accurate statistics. The difficulty is more heightened by the fact that the use of salvarsan does not extend as yet over a sufficiently long period.

Each leper entering the Hospital of Andreas Sygros is carefully examined about his past and about his family history. This examination always proves that leprosy is congenital. It is surprising to witness the capacity of the personnel of this hospital, consisting of Dr. Photeinos, Dr. Evangelou, Dr. Petropoulos and Dr. Tsamaloucas, in diagnosing the disease at first sight. The latter especially is known in his circle as the Laconian Dog of Lepers. In the diagnosis, sight,

touch and smell are applied, for it is known that a leper has a particular and characteristic smell which cannot be mistaken by a man who is trained in this line. In this hospital lepers are not segregated from patients of other diseases. On the contrary they are allowed to come in contact with each other, and they talk about their trouble to any person with no shrinking or restraint. By all leprosy is regarded as any other common disease. No particular care is taken, and when the syphilitic is treated the leper is laid down on the same table, and vice versa.

The women, who are more sensitive than the men, paint their eyebrows when the hair has fallen. Peasant women, who wear a kind of scarf over their heads, lower this a little over their forehead to hide their disfiguration.

In closing, I wish to express the hope that the Greek government may continue to take good measures and to apply them earnestly and thoroughly in behalf of the several hundreds of its leprotic citizens and to the safety and honor of Greek society and state.

Book Reviews.

Pathological Technique, Including Directions for the Performance of Autopsies and for Clinical Diagnosis by Laboratory Methods. By F. B. MALLORY, M.D., Associate Professor of Pathology, Harvard Medical School; and J. H. WRIGHT, M.D., Pathologist to the Massachusetts General Hospital. Sixth Edition, illustrated. Philadelphia and London: W. B. Saunders Company. 1915.

The new edition remains in appearance like its predecessors. It contains, however, a number of additions not of extreme importance, although as is customary with the authors of this work, these methods are of proved usefulness: for instance, Bielschowsky's silver impregnation method for nerve fibrils, Bensley's technic for cell granules and mitochondria, Herxheimer's rapid method for staining fat, and the various new methods of importance in the diagnosis of syphilis and demonstration of the treponema pallidum.

There are a number of new and very excellent photomicrographs.

A discussion of this well known authoritative and standard work would be superfluous. No pathological laboratory in school or hospital is without it. The fact that the book is kept up to date by its authors is sufficient recommendation for such a popular and constantly praised work.

House Flies and How They Spread Disease. By C. G. HEWITT, D.Sc., Dominion Entomologist,

Ottawa, Canada. Cambridge, England: University Press. 1912.

This belated volume in the series of Cambridge manuals of science and literature, presents at a seasonable time of year a brief popular study of the house fly as a disseminator of infection.

It may be regarded as a preliminary sketch for the author's larger technical work on "The House Fly," reviewed in the issue of the JOURNAL for June 10, 1915. Unlike the latter work, however, and the other larger volume by Howard, the present manual aims chiefly at such description of the fly and its life habits as shall be of value in the education of the intelligent public to the importance of this ectoparasite and of its extensive destruction. It is well illustrated with 19 figures in the text and concludes with an excellent brief bibliography on the subject.

The Elements of Military Hygiene. By P. M. ASHBURN, Major Medical Corps, U. S. A., Second edition. Boston and New York: Houghton Mifflin & Co.

This monograph on military hygiene was originally written and especially arranged for officers and men of the line, with the purpose of informing and interesting them in matters of camp sanitation, that they might coöperate more effectively with the medical staff. During the six years which have elapsed since its first appearance, the science of military hygiene has made noteworthy progress and its advances are incorporated in this second edition. Much of the text has been revised and rewritten and a supplementary chapter has been added on the prevention of mental and nervous diseases. The volume should continue its usefulness not only to rankers but to medical officers especially in the volunteer service and the militia.

The Diagnosis and Treatment of Tropical Diseases. By E. R. STITT, A.B., Ph.G., M.D. Philadelphia: P. Blakiston's Son and Company. 1914.

This clinical manual by a medical director in the United States Navy is a valuable brief textbook in an important branch of medicine which has rather recently become conspicuous in the professional field. It is divided into two parts, the first dealing with a description of tropical diseases and their treatment, with special emphasis on epidemiology and prophylaxis; the second with the diagnostics of tropical diseases, their clinical side being presented from the standpoint of signs and symptoms which are connected with anatomic or clinical groupings rather than with the individual disease. The work is well illustrated with 86 text figures and should prove an extremely valuable practical manual, especially for field work in the tropics.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, JULY 8, 1915.

EDITORS.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

WHOOPIING-COUGH.

WHOOPIING-COUGH is apt to be looked upon by those who have not inquired into the matter as a not very serious affection, but when one finds that it annually destroys the lives of no less than ten thousand American children it assumes an entirely different aspect. While it is usually less fatal than scarlet fever or measles, in some seasons the mortality from it is as great as from either of these affections. Like them, it is often attended by grave complications and sequelae and not infrequently, even when there may have been no complications, so reduces the vital resistance as to leave the patient an easy prey to any chance infection or other source of disease. Pertussis is especially dangerous for infants, and ordinarily in infants and young children the mortality from it is quite as high as that from scarlet fever.

As a result, however, of the isolation, in 1906, of the Bordet-Gengou bacillus, which is now recognized by the greater number of authorities as

the causative agent of the disease, it would seem that a new era in its prophylaxis and management is opening before us. Thirty years ago Goodhart (*Guide to the Diseases of Children*, 1885) remarked: "The remedies now in vogue for the second stage are in no sense specifics; they control the violence of the paroxysms, but have no destructive action upon the supposed germ which causes them. But if the disease be due to a germ, and the behavior of the disease is certainly in favor of this view, then it is to be hoped that a specific will one day be found, and obviously any drug exhibited with such an object must be applicable at any time during the life of the germ." The discovery of the specific bacillus has naturally been of service in increasing our general knowledge of whooping-cough. Thus, if this etiology be conceded, it is found that, as in the case of scarlet fever, the period of infectiousness has been overestimated. In a paper published in the *New York Medical Journal* for May 22, Dr. Paul Luttinger of the research laboratory of the New York City Health Department states that the Bordet-Gengou bacillus is most often met with in the sputum in the catarrhal stage and rarely later than the first week of the paroxysmal stage, and this fact has been confirmed by various other observers.

In the early part of last year the pediatricists of New York, profoundly impressed with the extent of the ravages of the disease, and believing that by systematic effort a distinct improvement in the situation could be effected, made an urgent appeal to the health department to take the matter up and devote its most serious attention to it. The department promptly assented to this request, and a survey conducted by the bureau of infectious diseases disclosed that among the chief reasons for the continued prevalence of whooping-cough were the following: Ignorance of the general public regarding the menace of this disease, insufficient attention, on the part of physicians and parents, to the isolation of the patient during the early period of the disease, lack of suitable dispensaries for patients ill with the disease, and neglect, in a large proportion of cases, to notify the health authorities. A special clinic for whooping-cough was then established in connection with the research laboratory, and this afforded an opportunity to follow up the patients in their homes. A large number of additional cases, which had not reached the notice of the health department, were thus discovered, and, in short, it was found that only about one-

quarter of the cases of whooping-cough occurring had been reported. It was realized, however, that physicians were not very largely responsible for this poor showing, inasmuch as it was not usually customary among these people to call in a physician for this disease. For some time past all cases of the disease reported by dispensaries, as well as all cases known not to be under the care of a private physician, have been kept under supervision by the district nurses of the bureau of infectious diseases; the nurses leaving cards of instruction and charging the family to keep the child quarantined for one week from the day on which the whoop appears. A week after the first appearance of the whoop permission may be given for the child to leave the premises, provided it is accompanied by an older person who will see that it does not play with other children, enter other homes, attend places of amusement or ride on street cars.

In the paper referred to, Luttinger gives a report of the results met with at the whooping-cough clinic from its opening in August to the end of the year 1914. In the treatment, drugs were employed in some of the cases and stock vaccines prepared from the specific bacillus in others, while in some instances both were given, and it is stated that these vaccines seem to have shortened the duration and severity of the paroxysmal stage; the average duration of the whoop being twenty-five days, as against forty days in those treated with drugs. To be successful it was found that the vaccine must be given in large doses. At first an initial dose of fifty million was given, but later this was increased to 250 million. In a small series of cases the vaccine was used successfully as a prophylactic, and in the prophylactic cases three large injections were given at three-day intervals; the first dose being 500 million, the second one billion, and the third two billion. It seems to have been the general experience that specific vaccines are of greater efficacy in prophylaxis than in the actual treatment of whooping-cough, but it is not to be expected that from any vaccine results can be obtained equal to those from a serum like diphtheria antitoxin. It would seem probable, from the experience at this clinic, that in some at least of the instances in which the vaccine was without beneficial effect, the reason for the failure has been the insufficiency of the doses employed.

At the conclusion of the report the belief is expressed that further experiments, with the view of obtaining more effective vaccines, and a

closer coöperation of the profession in public health education, will help largely in the eradication of this scourge of childhood. As the studies progressed the necessity of more whooping-cough clinics, and of a pertussis hospital, became more and more apparent. Information just received is to the effect that the good results previously noted at the whooping-cough clinic in New York from the use of pertussis vaccine have continued unabated to the present time; in fact, they have been even better since certain modifications have been made in the preparation of the vaccine. Dr. Luttinger writes: "The applicants for treatment recommended by private physicians and institutions are so numerous (as many as eighty on a single afternoon recently) that we are fast outgrowing our present quarters and our appropriation. Regarding prophylaxis, while none of the vaccinated contracted the disease, we cannot be absolutely sure of the protective value of the vaccine until we have an opportunity to compare vaccinated and unvaccinated cases during some circumscribed outbreak of the disease in an institution." It may be remembered that about a year and a half ago Dr. A. F. Hess of New York reported that in such an outbreak in an infant asylum, while the vaccine treatment did not appear to be of curative value, it proved of considerable prophylactic value. Of the 400 children in the institution, 244 had the vaccine administered to them prophylactically—in every instance before there was any sign of an attack—and of these, 20 developed the disease.

TUBERCULOSIS.

THE eleventh annual meeting of the National Association for the Prevention and Control of Tuberculosis was held on June 14, 15 and 16 in Seattle, Wash., and was attended by about 400 delegates from all parts of the United States. At the evening session on June 14 the principal address was presented by Dr. Edward O. Otis of Boston on "The Child and the Community;" another by Sherman G. Kingsley of Chicago on "The Importance of Ventilation in Schools;" and a third by Dr. Enrico Castelli of New York presenting the results of his experimental work in the medical school of Genoa, Italy.

On June 15 Dr. George M. Kober of Washington, D. C., president of the Association, in his

annual address called attention to the steadily diminishing ravages of tuberculosis throughout the United States.

"Tuberculosis in all its forms carried off during the year 1913 a total of 143,000 victims in the United States, which signifies the presence of approximately 1,430,000 consumptives with an economic loss of at least \$214,500,000. Great and grave as the problem may appear, there is certainly hope when we consider that the death rate from this disease has been reduced from 326 per 100,000 population in 1880 to 146.6 in 1913, which means that if the former rate had been continued the number of deaths from this cause would have been 322,027 instead of 143,000 in 1913, equivalent to a saving of 179,027 during one year."

At the conclusion of his address Dr. Kober presented the following recommendations for immediate action on the part of the Association:

"1. In view of the fact that from six to seven per cent. of the samples of the average market milk contain bovine tubercle bacilli, let us urge, by education and otherwise, that all milk, unless derived from tuberculin-tested animals, be pasteurized or scalded.

"2. Since the mortality from tuberculosis among inmates of unsanitary homes is often double and treble that of the general population, it is our duty to see that the building regulations are so modified as to prohibit the renting of houses unfit for human habitation.

"3. Because of the fact that nearly one-half of the 143,000 deaths from tuberculosis in 1913 occurred among the industrial workers, who constitute about one-third of the population, we should strongly urge the enactment and enforcement of laws for the removal of dust and fumes, the foes of industrial life."

With regard to the infection of children by bovine tuberculosis it may be noted that the British Royal Commission on tuberculosis has recently reported that not only are infants and children especially endangered by this form of infection, but that adults may also be directly infected with the bovine type of the disease. The Imperial German Commission on tuberculosis has also recently reported that of 84 children examined by them, 21, or 25%, had derived their infection from bovine sources.

Drs. Park and Krumweide of the New York City Health Department estimate that at least 300 children die every year in New York City from tuberculosis. Dr. Hess of the same city found that of 107 samples of raw milk obtained from as many different dealers, 16% of them could produce tuberculosis since they contained living tubercle germs. Dr. Churchill of Chicago reports that the records of surgical tuberculosis

for the year 1913 at the Children's Memorial Hospital showed that there were 64 operations on bone and joint tuberculosis, the kind that most often has been found to come from bovine sources. Dr. Brown of Saranac Lake considers that 8% of all cases of tuberculosis are of bovine origin. The Chicago Health Department reported that for the year 1910 the total number of milk samples examined showed 8.9% to contain tubercle bacilli. These were all in the raw milk samples, as the pasteurized milk showed none.

In the conclusion of his address Dr. Kober also advocated the following special measures to be undertaken for the prevention of tuberculosis by states and municipalities:

"1. Compulsory notification of cases to the health authorities as soon as the disease is recognized. The health authorities should also resort to disinfection of the home and personal effects, especially upon the death of the patient or vacation of the premises.

"2. The enactment and encouragement of laws against expectoration, coughing into the faces of persons, and the common use of individual drinking cups are called for. Provisions should be made for individual drinking cups or fountains, and for suitable spittoons and their disinfection in all public buildings. The public should not cultivate an exaggerated fear, but has a right to insist upon clean and decent precaution.

"3. The sanitary condition of hotels, lodging houses, theatres, churches, schools, ambulances and passenger service should be under the control of the health department, and house cleaning should be accomplished as far as practicable by the vacuum system.

"4. Marriage with a tuberculous person should not only be discouraged, but prohibited by law. A tuberculous mother should not nurse or kiss her infant, and in the selection of a wet nurse a certificate of health should be demanded.

"5. Isolation of tuberculous patients should be insisted upon in hospitals, asylums and public institutions. In private life, the patient should occupy at least a separate bed, use separate eating and drinking utensils, and neither receive nor give kisses. Careless and unteachable cases should be cared for in hospitals."

In his annual report as secretary of the association, Dr. Charles J. Hatfield stated that in spite of the universal financial depression the

year has been favorable for the work of the organization.

"Field secretaries have operated in more than 20 different states; over 100,000 churches have coöperated in the Tuberculosis Day movement, and the Red Cross Christmas Seal campaign has resulted in an increase of 15% over the previous year. The total number of stamps disposed of at the last sale was 53,000,000, netting practically \$530,000 for the tuberculosis movement. The membership of the National Association now numbers more than 2,400, including those most actively interested in the anti-tuberculosis work scattered throughout the United States and in almost every country of Europe and Asia, and even down in South Africa and Australia."

The National Association for the Study and Prevention of Tuberculosis has issued a statement warning consumptives not in adequate circumstances against traveling in the West and Southwest in search of health. They state that from 40% to 90% of all deaths from tuberculosis in the West and Southwest are of natives of other states who have migrated there, many of them hopelessly incurable and without sufficient funds to support them. They call attention to the fact that tuberculosis can be cured in any part of the United States, and it is far better for a consumptive of moderate means, such as the average working man, to go to a sanatorium near at home, than to go West and live in a more favorable climate without proper food or medical care.

LEPROSY.

IN another column of this issue of the JOURNAL we publish two articles on leprosy presented at a recent meeting of the Suffolk District Medical Society; one, by Dr. Honeij, deals particularly with local conditions in Massachusetts in relation to the prophylaxis and care of the disease; the other, by Dr. Katsinos, presents a historic review of leprosy particularly in Greece, with emphasis upon what the author regards as evidence of its hereditary nature. It is interesting in this connection to note the action which has recently been taken in Russia with regard to the permission of marriage among lepers. The Russian Medical Council, according to a statement in the *Lancet* of June 19, has expressed its opinion that

the hereditary factor in leprosy is trivial in importance, even in marriage between cousins, both of whom are, at the time, lepers. Moreover in such cases the birth rate is exceedingly low, which still further reduces the likelihood of such transmission. The *Lancet* expresses itself editorially as essentially in accord with the opinion of the Russian Medical Council.

"There can be little doubt that the best way of isolating lepers in affected countries is to intern them, under proper medical supervision, in special colonies or settlements where they can, as far as is practicable, lead active and useful lives, engaged in farming and other suitable occupations. Leper asylums and such institutions are best reserved for cases of old and advanced disease where incapacity for employment has been brought about by the ravages of the malady. In the leper colonies or settlements patients of both sexes have to be isolated, and we would raise no objection under certain conditions to the union of these persons if they desired to marry. Young leprous adults of both sexes are more likely to become more hopeful, contented with their lot, if they have a home of their own and a family life, even of a limited extent. The fertility of leper marriages is not great, and as the leprosy advances impotence usually develops. It is imperative, however, that arrangements should be made in advance, and the reasons carefully explained beforehand to the leprous parents, to remove at once any newly born infant from the custody of its mother to a distant home provided by the authorities where the child may grow up without danger of acquiring the infection from its maternal parent. Leprosy is not believed to be a hereditary disease, but close and intimate contact, such as that between a mother and child, is regarded as affording the surest means of conveying the infection from one person to another. We freely admit that the parting of the leprous mother from her newly born child would be painful to her, but in the interests of the child such parting is absolutely necessary and should be regarded as inevitable by both parents. The lot of the leper is admittedly a hard one, and whatever can be done, consistent with medical knowledge and science, should be done in order to alleviate as far as possible the hardships of these unhappy sufferers. With the indicated reservations, we agree with the Russian Medical Council in their view that the marriage of one leprous person with another is, under certain circumstances, permissible."

With regard to the treatment of leprosy, attention may be called to the biannual report of the Hawaiian board of health for the period ending in June, 1912, in which the medical superintendent of the leper colony at Molokai, gives an account of the various remedies there used.

the methods of their application, and the results secured. For a decade warm sulphur baths have been a routine hygienic method at the settlement, and while not specifically curative of leprosy, are grateful to the patient, cleansing, and ameliorative of the systemic as well as the local effects of the disease.

After reviewing the number of patients treated for intercurrent diseases, Dr. Goodhue, the medical superintendent, continues:—

"General surgical cases have had the usual attention at bi-weekly surgical clinics, and considerable work has been done in the surgery of special organs, principally as observed in the nose and throat. A system of anatomical charts for purely leprosy cases has been instituted in which lesions peculiar to the disease are marked to code diagram, the key to which is indexed for ready reference. Annotations are added where deemed necessary for further amplification.

"Approximately 75% of the inmates at the Leper Settlement are receiving special treatment for leprosy, and a number of patients now receiving tonic and nutritive remedies, are also taking specific treatment."

"Chaulmoogra oil is the most popular remedy. Strychnine in graduated doses, or elixir of iron, quinin and strychnine, according to preference. Both are decidedly ameliorative.

"Anti-leprol is a refined product of chaulmoogra oil, and is tolerated much better by the stomach.

Of the newer remedies employed, Dr. Goodhue mentions thoradin paste and ointment and anti-leprol. He believes the latter superior to chaulmoogra oil for the following reasons:—

"First. It is a purified product of chaulmoogra oil, and as such can be taken without gastric irritability.

"Second. Dosage may be increased to the maximum more rapidly and without impairing the appetite and consequently digestion and assimilation, as occurs so frequently with the ingestion of chaulmoogra oil.

"Third. Very much larger doses may be taken, so that the disease comes under the influence of treatment more quickly.

"Fourth. The oil is uniform, does not thicken and form a resinous deposit.

"Fifth. Easy to dispense, as it requires no previous treating to effect solution.

"Anti-leprol has not become so popular here as chaulmoogra oil treatment for the reason that the latter has acquired a wonderful prestige, but a number of patients who are unable to retain chaulmoogra oil, have had no difficulty in taking large doses of anti-leprol, and are thus prevented from becoming discouraged and refusing all treatment."

Finally Dr. Goodhue describes the use of serum and anti-toxin emulsion. The serum is ob-

tained by the application of sinapisms, aseptic withdrawal of the fluid, precipitation of possible bacilli by centrifuging, and injection of the sterilized supernatant liquid. At first the serum was given diluted with normal salt solution; later it was given pure without ill effects. The purpose of its use is the hope of increasing bacteriolytic activity. The following objections to its use have been noted.

"First. It will not keep well unless on ice.

"Second. General dislike of most Hawaiians to injections.

"Third. It is difficult to obtain a regular supply to be depended upon. The anti-toxin emulsion consists of carefully selected non-neurotic, excised lepromata, which are thoroughly cooked, desiccated in hot-air sterilizing oven, pulverized and made into a definite emulsion with glycerin, and given *per os*.

"Improvement consists in greatly lessened digital flexion and inter-osseous atrophy as well as general body-tone.

"From clinical observation I believe that an excess of sodium chloride or any other article of diet preserved through the medium of this drug greatly favors leprosy bacillary activity and proliferation. Certainly it is true that foods which disturb the alkalimous balance and increase the reaction in the circulating and other fluids of the body, largely neutralize the ameliorative action of chaulmoogra oil in leprosy."

HAY FEVER.

IN another column of this issue of the JOURNAL we publish an important original article by Dr. Joseph L. Goodale of Boston on the pollen therapy of hay fever, a subject on which he has made individual research of great value, and upon which he has presented previous communications. Dr. Goodale divides the hay fever season into four periods: First, that of the early flowering plants, chiefly trees and shrubs, of April and May; second, that of the flowering grasses in May and June; third, that of the mid-season flowers of July and August, chiefly Compositae; and fourth, that of the late Compositae of August until frost. This paper, then, representing research recently completed, is in season for the aid of the profession in the treatment of hay fever during the third and fourth periods this year.

Dr. Goodale goes at length into the technic of collecting the pollen of various plants, preparing the extracts, employing these extracts in the di-

agnostic tests and in the treatment of the condition. He also discusses the question of anaphylaxis in relation to this method of treatment. Perhaps most interesting of all is his discussion of the biologic relation between the different plant proteids in the production of the disease. It is in this field that Dr. Goodale's most valuable and original work upon this subject has been done. He presents in an interesting diagram the phylogenetic relationship of the different plant orders and families and suggests the far-reaching possibilities of the application of the knowledge of this relationship to the treatment of hay fever by injection of pollen extracts. Dr. Goodale has been particularly qualified for the successful performance of this important piece of medical research, since to it he has brought not only his professional skill but his special knowledge as an expert botanist.

CANCER.

THE attention of the profession is called to the fact that the next issue of the JOURNAL will be published as a special Cancer Number. It will contain a series of special original articles by well known authors on various topics connected with the hygienic, clinical and surgical problems presented by cancer. This publication is in conformity with a plan originated by the Philadelphia State Medical Society whereby 73 American medical periodicals, during the current month, will issue editions devoted to this subject. The importance of this intensive movement on the part of the medical press is of considerable moment, since it marks a definite and generalized effort to emphasize to the medical profession and the intelligent public the seriousness of cancer and the urgent desirability of its prompt diagnosis and treatment and its prevention by early prophylaxis.

MEDICAL NOTES.

MEASLES STILL PREVALENT IN NEW YORK.—There were 1277 deaths and a death rate of 11.47 per thousand of the population reported during the past week as against 1258 deaths and a rate of 11.75 in the corresponding week in 1914, an increase in the absolute number of deaths of 19 and a decrease in the rate of .28 of a point, which is equivalent to a relative decrease of 31 deaths.

The only noteworthy feature of the week's mortality was the increase in the deaths from

measles and broncho-pneumonia, both causes being intimately associated one with the other.

Viewed from the point of age grouping the mortality of children under one year of age was considerably higher than the corresponding week in 1914, there being an increase of 49 deaths reported. The mortality of the other age groups was slightly below that of the previous year.

The death rate for the first twenty-six weeks of 1915 was 14.21 per one thousand against the rate of 14.79 during the corresponding period of 1914, a decrease of .58 of a point.

NATIONAL COMMITTEE FOR THE PREVENTION OF BLINDNESS.—The sixth annual report of the New York State Committee for the Prevention of Blindness covers the period from Nov. 1, 1913, to January 1, 1915, and records the history of its six years of work and present affiliation. On Jan. 1, 1915, it was consolidated with the American Association for the Conservation of Vision, making of the two organizations one national body, to be known as the National Committee for the Prevention of Blindness. An income of \$15,000 has been provided to meet the expenses of the new national organization for the first year of its work. This organization is the natural outgrowth of the two committees above mentioned. The National Committee for the Prevention of Blindness, organized by the Russell Sage Foundation on April 27, 1908, was established to extend the work among laymen, instituted by the American Medical Association in its committee on ophthalmia neonatorum. The objects of this committee as defined were: "to ascertain the direct causes of preventable blindness, and to take such measures, in cooperation with the medical profession, as might lead to the elimination of such causes"; and this was to be done through investigation, education, publicity, legislation, and coöperation. As its work increased and its membership grew it was reorganized as an independent state organization, known as the New York State Committee for the Prevention of Blindness. Early in its history it became the recipient of requests from various states throughout the union for material in the work of the prevention of blindness, which work it could not, as a state organization, adequately take up. In December, 1910, there was organized a national association, called the American Association for the Conservation of Vision, which, owing to various causes, became inactive within a few months. A plan to consolidate the two committees was brought to the attention of the Rockefeller and Russell Sage Foundations, who gave assurance of some financial support, and arrangements were completed Jan. 1, 1915. Mr. Edward N. VanCleve, president of the Ohio State Commission for the Blind and superintendent of the Ohio State School for the Blind, is managing director of the committee. The committee proposes during the present year to continue its

study of the occurrence and results of ophthalmia neonatorum; to assist in securing the enforcement of the law requiring this disease to be reported early; to secure provisions whereby reported cases may be adequately and promptly treated; to extend educational work as to the methods of prevention and cure of this disease; to support or initiate legislation which shall provide for the standardization of midwife schools by the State Department of Education; and to continue its study of unnecessary blindness and visual impairment resulting from wood alcohol, trachoma and other infections, industrial accidents and inadequate lighting; and to take such measures as lie in its power to aid in eliminating such causes.

A NEW PUBLICATION.—The publication of a new journal, the *Hospital News* is announced. Its editors-in-chief are Wilfred M. Barton, M.D., and Walter A. Wells, M.D., and its associate editors are Tom A. Williams, M.D., Francis R. Hagner, M.D., W. P. Carr, M.D., James A. Gannon, M.D., Robert Scott Lamb, M.D., C. Augustus Simpson, M.D., S. B. Muncester, M.D., Prentiss Willson, M.D., Thomas A. Lowe, M.D., John O. Skinner, M.D., Harry S. Lewis, M.D., Philip W. Newton, M.D., Kiev, Russia.

ST. LAWRENCE STATE HOSPITAL.—The annual report of the St. Lawrence State Hospital, Ogdensburg, N. Y., for the year ending Sept. 30, 1914, states that 2460 patients were treated during the year. The number of patients discharged recovered was 117 and 82 others were sufficiently improved to justify their return to their homes and former occupations; 30 others, who had shown no improvement but whose mental condition had become stationary, were discharged to the custody of friends. The voluntary patients admitted during the year numbered 38—27 men and 11 women. There were in all 75 voluntary cases under treatment. Of the patients admitted during the year 49.5% were subsequently returned to their homes benefited by treatment. The entering class of the nurses' training school numbered 39 and the graduating class numbered 9. The number of pupils in the training school at the end of the year was 65.

AMERICAN SOCIAL HYGIENE ASSOCIATION PRIZE.—In the issue of the *JOURNAL* for April 29, 1915, we published an account of the offer of a prize of \$1000 by the American Social Hygiene Association, to be awarded to the author of the best original pamphlet on social hygiene for adolescents between the ages of twelve and sixteen. The committee of judges for this prize has just been announced and includes the following physicians: Luther H. Gulick, M.D., president, The Camp Fire Girls, New York, formerly director of physical training in the New York City Public Schools; Milton J. Rosenau, M.D., professor of preventive medicine and hygiene, Harvard

Medical School, Boston; and Victor C. Vaughan, M.D., president of the American Medical Association, dean, Department of Medicine and Surgery, University of Michigan.

DECREASE OF FOOT AND MOUTH DISEASE.—Report from Washington, D.C., states that on June 28 an extensive relaxation of the federal quarantine against foot and mouth disease became effective. Interstate movements of livestock were resumed between "restricted area" and points in "free" and "closed" area for immediate slaughter. Shipments for any purpose have been permitted to all points except those in "closed" area. In Illinois a large area, which, however, does not include the Union Stock Yards, was made free. All Indiana became free, including the belt stock yards at Indianapolis. In Ohio, the Union Stock Yards at Cincinnati and the Cleveland Union Stock Yards became restricted area to handle livestock for immediate slaughter only. The Pittsburgh Union Stock Yards are in the same classification. The hog and sheep divisions of the West Philadelphia Stock Yards became modified area. Stock yards at Milwaukee and Cudahy, Wis., passed to the restricted classification. Other changes affected Maryland, Montana, New Jersey, New York, Rhode Island, Virginia and West Virginia.

AWARD OF THE KUSSMAUL MEDAL.—It is announced that the Kussmaul medal and the prize from the Kussmaul endowment in surgery have been awarded by the faculty of the University of Heidelberg to Professor Braum of Zwickau.

EUROPEAN WAR NOTES.—On June 15 a unit of 32 surgeons and 75 trained nurses, organized at Chicago, sailed from New York aboard the steamer *Nieu Amsterdam* for Falmouth, England. This unit, which will form a part of the British Army Medical Corps, is in command of Dr. James M. Neff of Spokane, Washington, and Dr. George B. Davis of Chicago, both of whom have been commissioned lieutenant colonels. This Chicago unit will probably be assigned to a base hospital in France.

Report from New York on June 17 states that Dr. Kirby-Smith of Sewanee, Tenn., who has recently returned from Serbia, says that the typhus epidemic in that country is now well under control. At the time of his arrival in Belgrade there were 1500 cases of the disease in a single hospital with only four physicians in attendance, and the deaths averaged 35 or 40 a day. He estimates that there has been a total of nearly 20,000 deaths from the disease.

On June 16 it was announced by the Serbian general consulate of New York that an additional sum of \$5000 had been assigned by the committee of mercy to the Columbia University Relief Expedition. This, with \$10,000 already raised and gifts from other sources, makes a total of \$22,500 available for this expedition, which will soon sail on the steamship *Thessaloniki*.

An enthusiastic contemporary in the daily press, in an editorial describing with praise the work of Americans in the relief of the distressed peoples of Europe, refers particularly to Dr. Richard Pearson Strong, "who, it seems, has gripped the Serbian typhus plague with a firm and steady hand, and is snatching order out of chaos and cheering a whole nation with one foot in the grave." The mixture of this metaphor, which somehow reminds one of the horrible examples in books on rhetoric, must surely be pardoned for the sake of the sincerity of its intended commendation.

Report from London on June 28 states that Dr. W. J. Maloney of New York, who has been serving as a surgeon with the allied forces of the Dardanelles expedition, has been seriously wounded and is now lying in hospital at Alexandria, Egypt.

On June 29 Dr. Henry L. Davis of Lynn, Mass., sailed from New York for England to join the British Red Cross in the field.

THE MEDICAL LIBRARY ASSOCIATION.—The Medical Library Association, consisting of a membership of 52 libraries and 46 individuals, has completed 18 years of its existence and proved the worth of its object,—to foster medical libraries and the maintenance of a system for the exchange of medical literature among them. In other words, it has formed a clearing house through which books, journals and reprints, or lists of them, may be sent from one library to another. Lists of material for exchange are sent mostly to members of the Association, this method having been found more useful than the system of quarterly bulletins issued formerly. By careful use of funds the treasurer's report for the past year showed a substantial balance with which it is planned to extend still further the work of the Association. Lieut.-Col. C. C. McCulloch, Jr., of the library of the Surgeon-General's office, is president of the Association and Dr. John Ruhrah of Baltimore is secretary and treasurer.

DECLINING SCOTTISH BIRTH RATE.—The recently published annual report of the registrar general for Scotland shows that between the middle of 1912 and the middle of 1913 the total population of Scotland decreased 12,945. Moreover, there was a decrease of 32,732 between 1911 and 1913. During the year 1913 the total number of living births in Scotland was 120,516, which was 2274 less than the number for 1912 and 5230 less than the mean of the preceding five years.

"A striking fact was that the registered births of the year 1913 were less than those of all previous years since 1873; a maximum number of 133,525 births was registered in 1903, and compared with this the present year was 13,000 short. Fifty-one per cent. of the children registered were male and 49% female. The birth rate for the year was 25.49 per 1000 of the esti-

mated population. Legitimate children accounted for 92.91%, and the illegitimate for 7.09%; the number of the latter was less than in all years since 1903, and the illegitimate rate was less than those of all years since 1908. There were 1175 more marriages in 1913 than in 1912, and 296 more than the mean of the numbers of the preceding five years (1908-1912); in fact, it was the largest number of marriages registered in Scotland in any year since the introduction of national registration. The marriages thus reached their highest and the births their lowest level in 1913; this is a fact of great significance in its bearing upon the decreased productivity of the Scottish people. The deaths for 1913 numbered 73,069, or 729 more than in the previous year; the death-rate was 15.45 per 1000 of the estimated population."

These figures, it is to be remembered, concern a period which was in no way affected by the present European War, and, therefore, indicate in times of peace a tendency towards steady decrease in birth rate comparable with that observed in France, England and the United States. The effect which the war may have upon this decline in the future cannot now be definitely prognosticated since there are theoretic reasons for exactly opposite effects between which it is probably impossible now to judge, since the ultimate social, political and biologic effects of the war cannot be surely appreciated until after its close.

BOSTON AND NEW ENGLAND.

INSTRUCTIVE DISTRICT NURSING ASSOCIATION.—It had been planned by the Boston Instructive District Nursing Association to institute on June 28 a course of training for nurses in the care of tuberculous patients, but there were so few applicants that this proposed course has been postponed for the season.

HARVARD MEDICAL ALUMNI OFFICERS.—The annual meeting of the Harvard Medical Alumni Association was held at Harvard Hall, Cambridge, on Commencement Day, June 24. Dr. Frederick C. Shattuck of Boston was elected president, Dr. James B. Ayer treasurer, and Dr. Arthur B. Emmons, 2d, secretary for the ensuing year.

The forty-fourth annual meeting and dinner of the Harvard Dental Alumni Association, held the same day at Young's Hotel, Boston, were attended by 216 members. The following officers were elected for the ensuing year: President, Harold deW. Cross, '96; secretary, Frank T. Taylor; treasurer, Charles T. Warner; executive committee, Frank T. Taylor, '90, William D. Squarebriggs, '98, Leroy M. S. Miner, '04.

PLANS FOR THE BRADY LABORATORY.—On June 27 it was announced at New Haven, Conn., that plans have been completed for the new Anthony

N. Brady laboratory, which is to be erected at an estimated cost of \$125,000, and the construction of which it is expected will be begun this summer.

The building will be erected on the grounds of the New Haven Hospital, on land owned by the university, on which it is proposed to put up the new medical school buildings. It will be of brick and stone in the Georgian style, rectangular in shape, approximately 50 feet by 150. It will be arranged on a unit plan, the classrooms to consist of three or four units and the working rooms for the instructors and technicians one or two units. It will be constructed so that the partitions can be removed to alter the size of rooms.

The construction will be fireproof and the floors will be of concrete. Large windows have been provided for every room. By an ingenious arrangement of trenches and conduits the pipes for plumbing, compressed air, electrical lines, etc., can be gotten at in case of alteration without tearing up the building.

It will be a three-story building with basement and attic. The basement will contain students' lockers and toilet rooms, a storage museum for the department of pathology, a machine room, janitor's room, rooms for small animals and the columbarium. The first floor will contain the teaching room for pathology, the autopsy room, receiving room and the internes' working laboratory.

The second floor will contain a teaching room for instruction in clinical microscopy, working rooms for the staff of the departments of surgery and obstetrics, students' research rooms, etc. The third floor will contain working rooms for the other departments. In addition to the janitor's room in the attic there will be a roof garden for small animals that need to be kept in the open air.

THE SECOND HARVARD SURGICAL UNIT.—In the issue of the JOURNAL for June 17 we published the personnel of the second Harvard surgical unit, which finally left Boston on June 25 and on June 26 sailed from New York aboard the steamer *Noordam*, under command of Dr. Edward H. Nichols. This unit has been assigned to a base hospital at Woolwich, England, for the three months from July 1 to October 1, where it will be followed by similar units from Columbia and Johns Hopkins. All the surgeons will receive temporary commissions in the British army. After October 1 members of the unit may continue their work in France.

BOSTON FLOATING HOSPITAL.—The Boston Floating Hospital began the twenty-second season of its work by a trip down the harbor on Wednesday, June 30, and plans have been made to continue these trips daily throughout the current summer. The staff of the hospital is essentially the same as that of previous years and includes the following physicians:—

Dr. Henry I. Bowditch, chief physician in

charge of the staff; Dr. James Herbert Young, Dr. Edwin T. Wyman and Dr. John W. Hammond. The auxiliary staff includes the following: Dr. Dana W. Drury, otologist; Dr. James S. Stone, surgeon; Dr. Beth Vincent, assistant surgeon; Dr. James B. Ayer, mental diseases; Dr. Edwin H. Place, contagious diseases; Dr. Robert G. Loring, ophthalmologist; Dr. William T. Councilman, pathologist; Dr. John Henry Bufford, dermatologist; Dr. Frederic W. Howe, director food laboratory.

Dr. Paul W. Emerson will again be house physician. The senior house officers are: Dr. M. Sehan, Infants' Hospital, Boston; Dr. Carl H. Laws, Boston, and Dr. Warren P. Sisson, Peter Bent Brigham Hospital; the junior house officers—Dr. J. Sumner Teter, Arlie Vernon Bock, Dr. C. N. Moore, all of Boston; senior externe, Dr. James W. Bruce, City Hospital, Louisville, Ky.; junior externe, Alton Goldbloom, Montreal; and the medical assistants, Dr. J. Aloysius Drooz, Albany, N. Y.; Samuel A. Cohen, Roxbury; and Burton E. Lovesey, Philadelphia.

Brenton R. Lutz is chief of the food laboratory; Alfred W. Bosworth, A.M., the biological chemist; and Garm Norbury, the bacteriologist.

It is earnestly to be hoped that this important and particularly picturesque medical charity may continue to be well supported by a generous public in spite of the financial conditions incident to the European War.

Massachusetts Medical Society.

PROCEEDINGS OF THE SOCIETY.

ANNUAL MEETING.

First Day, June 8, 1915.

Clinics and demonstrations were held during the morning at the principal hospitals in Boston.

The annual meeting of the supervisors was held in the foyer of the Copley-Plaza Hotel, Boston, at 11.30 o'clock.

The annual meeting of the council was held in the foyer, at 12 o'clock noon.

Meetings of the sections were held in the Copley-Plaza Hotel, in the afternoon. The sections were officered and papers presented according to the following program:

MEETING OF THE SECTION OF MEDICINE.

Foyer, Copley-Plaza Hotel.

2.30 o'clock.

Officers of the Section of Medicine:

Dr. Elliott P. Joslin, Boston, *Chairman*.

Dr. James H. Means, Boston, *Secretary*.

Symposium on Heart Disease.

1. The Use of Digitalis in the Various Forms of Cardiac Arrhythmias.—Dr. Henry A. Christian, Boston.

2. The Relation of the Abnormal Heart Beat to Prognosis.—Dr. Paul D. White, Boston.
3. Treatment of Heart Disease.—Dr. F. C. Shattuck, Boston.
- Discussion.—Dr. John Sproull, Haverhill; Dr. Francis W. Palfrey, Boston; Dr. J. H. Pratt, Boston.

Attendance, 120.

MEETING OF THE SECTION OF SURGERY.

State Dining-Room, Copley-Plaza Hotel.

2.30 o'clock.

Officers of the Section of Surgery:

Dr. Paul Thorndike, Boston, *Chairman*.

Dr. Edward P. Richardson, Boston, *Secretary*.

1. Demonstration of a method by which fragments of needles lodged in tissues near the surface of the body may be localized by means of magnetism.—Dr. George H. Monks, Boston.

2. Acute Perforations of Ulcers of the Stomach and Duodenum.—Dr. W. E. Faulkner and Dr. I. J. Walker, Boston.

3. Traumatic Perforations of the Duodenum.—Dr. David Cheever, Jr., Boston.

4. Cholelithiasis: An Argument for Early Operation.—Dr. Joshua C. Hubbard, Boston.

5. A Brief Consideration of Acute Pancreatitis, with Case Reports.—Dr. C. E. Durant, Haverhill.

Discussion.—Dr. P. E. Truesdale, Fall River; Dr. D. F. Jones, Boston.

Attendance, 140.

MEETING OF THE SECTION OF TUBERCULOSIS.

Ballroom, Copley-Plaza Hotel.

2.30 o'clock.

Officers of the Section of Tuberculosis:

Dr. Albert C. Getchell, Worcester, *Chairman*.

Dr. John B. Hawes, 2d, Boston, *Secretary*.

1. Non-tuberculous Cases at the State Sanatoria.—Dr. Elliott Washburn, Superintendent Rutland State Sanatorium.

Discussion.—Dr. I. J. Clarke, Haverhill; Dr. C. C. MacCorison, Superintendent North Reading State Sanatorium; Dr. Charles E. Perry, Superintendent Hampshire County Sanatorium.

2. Errors in Diagnosis in Chronic Diseases of the Lungs.—Dr. John B. Hawes, 2d, Boston.

Discussion.—Dr. Allen G. Rice, Springfield; Dr. Frederick T. Lord, Boston; Dr. H. C. Clapp, Boston.

3. What Constitutes Tuberculosis in Childhood.—Dr. John Lovett Morse, Boston.

Discussion.—Dr. Walter C. Bailey, Boston; Dr. Dr. Cleveland, Floyd, Boston; Dr. F. B. Talbot, Boston; Dr. H. D. Chadwick, Superintendent Westfield State Sanatorium.

Attendance, 100.

Officers of the Sections for the ensuing year were elected by the Sections respectively as follows:

Section of Medicine: Chairman, Henry Jackson, Boston; Secretary, F. Gorham Brigham, Boston.

Section of Surgery: Chairman, C. E. Durant, Haverhill; Secretary, W. M. Boothby, Boston.

Section of Tuberculosis: Chairman, Albert C. Getchell, Worcester; Secretary, John B. Hawes, 2d, Boston.

The Shattuck Lecture was delivered in the foyer of the Copley-Plaza Hotel, in the evening, by Dr. Joel E. Goldthwait, of Boston, on "An Anatomic and Mechanistic Conception of Disease." (See BOSTON MEDICAL AND SURGICAL JOURNAL, June 17, 1915, page 881.)

At the close of the lecture there was an informal reception to the president and a popular concert in the ballroom, and refreshments were served, the attendance being 477.

Second Day, June 9, 1915.

The Society met at the Copley-Plaza Hotel for the exercises of the one hundred and thirty-fourth anniversary. The President, Dr. C. F. Withington, was in the chair, and about 130 Fellows were present during the morning.

The minutes of the last meeting were read and accepted.

The secretary announced that during the past year the Society had lost by death 52 Fellows, by resignation 25, by deprivation of the privileges of fellowship 48, making a total loss of 125. The Society had gained 203 Fellows as follows: Restoration by Council, 9; readmitted by Censors, 2; new Fellows, 192, a net gain of 78, making the total membership, 3582.

The president introduced Dr. Kate Campbell Mead, of Middletown, delegate from the Connecticut State Medical Society. A motion thanking thirteen Fellows for their unselfish and efficient services as experts in the defence of suits for malpractice against Fellows of the Society, passed by the Council on the previous day, was read by the secretary and voted unanimously.

Papers were read according to this program, being devoted to the following topics, viewed from the standpoint of Public Health and Preventive Medicine. Each speaker was limited to ten minutes.

1. The Work and Aims of the State Department of Health.—Dr. Allan J. McLaughlin, Boston.
2. Pneumonia.—Dr. Frederick T. Lord, Boston.
3. Infant Mortality.—Dr. John Lovett Morse, Boston.
4. Typhoid Fever.—Dr. M. W. Richardson, Jamaica Plain.
5. Preventable Heart Disease.—Dr. Roger I. Lee, Cambridge.
6. Tuberculosis.—Dr. Arthur K. Stone, Boston.
7. Syphilis.—Dr. Abner Post, Boston.
8. Contagious Diseases.—Dr. Eugene R. Kelley, Boston.

The Annual Discourse was delivered at twelve o'clock by Dr. Everett A. Bates, of Springfield, on "Some Perplexities in Modern Medicine." (See BOSTON MEDICAL AND SURGICAL JOURNAL, June 10, 1915, page 843.)

In the afternoon there was a combined meeting of the Sections of Medicine and Surgery in the Surgical Amphitheatre, Boston City Hospital, under the chairmanship of Dr. Elliott P. Joslin and the secretaryship of Dr. James H. Means, when the following program was presented:

COMBINED MEETING.

Symposium on Empyema.

1. The Medical Aspects of Empyema and Pulmonary Abscess.—Dr. F. T. Lord, Boston.
2. The Recognition of Pleural Disorders by X-rays, with Especial Reference to Empyema.—Dr. Percy Brown, Boston.

3. The Pneumodynamics of the Treatment of Empyema.—Dr. F. C. Cotton, Boston.

4. The Surgical Treatment of Chronic Empyema.—Dr. F. B. Lund, Boston.

5. Lung Abscess and Bronchiectasis from a Surgical Point of View; End Results of Acute and Chronic Empyema.—Dr. Wyman Whittemore, Boston.

Discussion.—Dr. George G. Sears, Boston; Dr. John Romans, Boston; Dr. James S. Stone, Boston; Dr. Frank L. Richardson, Boston.

Attendance, 140.

The Annual Dinner was served in the ballroom of the Copley-Plaza Hotel, in the evening, to 763 members and guests. The president made a short address and felicitously introduced the following speakers: His Honor Grafton D. Cushing, Lieutenant-Governor of Massachusetts; The Very Reverend Edmund S. Rousinaniere, Dean of the Cathedral Church of St. Paul, Boston; Mr. Charles H. Grandgent, Professor of Romance Languages in Harvard University; and Former President and Professor William H. Taft, of New Haven.

Adjourned at 11 p.m.

WALTER L. BURRAGE, *Secretary*.

ADMISSIONS REPORTED FROM JUNE 11, 1914, TO JUNE 9, 1915.

Year of Admission.	Name	Residence.	Medical College.
1915	Ahlstrom, Hjalmar	Quincy	12
1914	Allison, Carl Edwin	Wakefield	12
1915	Anderson, Victor Vance	Cambridge	37
1914	Andrews, Benjamin Franklin	Worcester	12
1915	Arey, Harold Carleton	Worcester	5
1915	Atwood, Blanche Louise	Worcester	12
1915	Anstett, James Cornelius	Spencer	7
1914	Ayers, Charles Elton	South Boston	12
1915	Bagnall, Elmer Stanley	Roslindale	12
1914	Baldwin, Edith Elizabeth	Springfield	33
1914	Barney, Willis Oliver	Boston	12
1914	Baxter, Clarence Pennell	Topsfield	12
1914	Bell, Conrad	Waltham	11
1914	Bell, Richard Dana	Somerville	11
1914	Berry, Charles Francis	Boston	7
1915	Blake, Francis Gibman	Roxbury	11
1915	Blake, James Eddy	Roslindale	17
1915	Boehm, Julius Benjamin	Boston	6
1914	Bonelli, Raymond Peter	Boston	12
1914	Boyd, Francis Peter	Springfield	12
1915	Bowen, Alfred Preston	Lynn	11
1915	Brindamour, Joseph Edmund	Holyoke	38
1914	Brown, Herbert Rutherford	Jamaica Plain	11
1914	Buck, Clifton Leon	Danvers	12
1914	Buckley, Daniel Joseph	Arlington	12
1915	Burns, Walter Linn	Lynn	11
1915	Caines, Richard John	Ridgway, Boston	12
1915	Carpenter, Robert John	North Adams	12
1914	Chamberlin, Harold Augustus	Worcester	12
1915	Chandler, Harold Beckles	West Newton	11
1915	Chase, Joseph Jr.	Weymouth	10
1914	Cheever, Austin Walter	Mattapan	11
1915	Chronquest, Alfred Peter	Danvers	12
1915	Clarke, Mary Ella	Malden	12
1915	Clarke, Willis Earle	Malden	12
1914	Combes, Edward Augustus, Jr.	Winthrop	12
1911	Cook, James Henry	Braintree	12
1911	Cook, John William	Mansfield	43
1915	Courie, Wadie Fardoul	Boston	35
1914	Coursey, Frank Rudolph	Boston	12
1914	Cox, Oscar Francis Jr.	Boston	12
1914	Croftree, Ernest Granville	Boston	11
1914	Creamer, William Henry	Fall River	11
1914	Cronin, Herbert Joseph	Cambridge	11
1914	Cunningham, Joseph Henry	Cambridge	11

Year of Admission.	Name	Residence.	Medical College.
1914	Cunningham, Thomas Edw., Jr.	Cambridge	11
1914	Cutler, John Francis	Worcester	12
1914	Cutler, Myron Fred	Southbridge	12
1915	Cutler, Raymond William	Worcester	12
1914	Davis, Henry Levi	Lynn	12
1914	Dawling, John Joseph	Boston	11
1914	Dunham, Adeline Frances	Cambridge	12
1914	Eaton, Henry Douglas	Stockbridge	17
1915	Eldam, Carl Hermann	Lawrence	43
1915	Ellison, Daniel James	Lowell	12
1915	Emery, William Edward	Beverly	14
1915	Emmons, Henry Manning	Jamaica Plain	10
1915	Fenton, Alfred Archibald	Walpole	22
1914	Finnerty, Charles William	Somerville	7
1914	Fleet, William Ernest	Cambridge	12
1914	Fleming, Edwin Ralph	Medford	20
1914	Forster, John Ferguson Cooke	Holyoke	24
1915	Fraim, Irving William	Worcester	12
1915	Fraser, Somers	Boston	11
1914	Gafford, James Frederick	Springfield	14
1914	Godfrey, Henry White	Auburndale	11
1915	Gosline, Harold Imman	Hathorne	11

Total, 52.

COUNCILORS, 1915-1916.

NOTE.—The initials M. N. C. following the name of a councilor indicate that he is a member of the Nominating Committee. V-P indicates that the member is a controller by virtue of his office of president of a district society, and so vice-president of the general society. C indicates that he is chairman of a standing Committee.

Correspondence.

THE AMERICAN WOMEN'S WAR HOSPITAL.

LAIGTON, SOUTH DEVON, ENGLAND, JUNE 15, 1915

My Editor: Dr. Howard and I arrived here without any misadventures and found a well appointed hospital running to full capacity nearly all the time. I found on my arrival that I had been promoted to Director of Unit D, so I am stationed here indefinitely now and shall not go to France after all. The hospital is beautifully situated in large, well-kept grounds so there is ample space for the patients to exercise in, and they all seem to do well in the sunlight and fine clean air which we have. We are only a few moments' walk from the water, Tor Bay, and from the hospital can see Torquay on the left and Brixham on the right. We get some very interesting cases and in fact receive them quite quickly from the front, usually in lots of from 50 to 100. They are sent across the Channel in a hospital ship to Southampton and are then transferred to a well-equipped hospital train and distributed along the line to the various hospitals. The cases are of various types—some medical cases, mostly those who have been "gassed," and incidentally "gassing" certainly does play the mischief with the men, as it apparently gives them a very acute and painful form of bronchitis, and they have great difficulty in breathing and in some instances their eyes are very severely affected. Nearly all of the wounds are infected, but after the bullets and pieces of shrapnel are removed they clear up very rapidly and the way in which septic compound fractures clear up is really marvellous. I have at present several very interesting cases on my wards, one in particular, a man who was shot by a shrapnel bullet through the lower end of the sacrum. The bullet dodged the rectum and landed in the bladder. There are no symptoms save a small stream of urination, when standing, and some pain. When he lies down the stream is all right and there is no pain save at the very end. I am getting some good x-rays on him and am waiting for a cystoscope to arrive from London before I operate on him. We have also several cases of nerve injury, so we see the unusual here, I am sending you one of the reports on the first 1000 cases in which you may be interested.

Sincerely yours,

D. P. PENHALLOW, M.D.

[The report which our correspondent encloses presents an interesting analysis of the first 1000 cases treated at the Hospital. Of these, 41% had perforating, and 59% non-perforating wounds. There were only three deaths.—EDITOR.]

THE DEATH OF MADAME DEPAGE.

BRUSSELS, JUNE, 1915.

My dear Colleagues: I have received from a large number of you and notably from the committees which you have formed, the most touching tributes of sympathy and of condolence for the catastrophe of the *Lusitania* in which my wife lost her life.

These tributes are so numerous and so unanimous, that I wish to express to you publicly my appreciation of them. I address myself to you, my dear colleagues, as the authorized representatives of the humanitarian sentiments which so honor the great American nation.

You all know, as I wrote to you when my wife left for America, for what purpose she accepted the mission which the Red Cross confided to her. In the presence of the unexampled miseries of which we have been the prey, she had resolved to solicit your fraternal assistance. You gave her that largely. I should

say "joyously" if the word could be pronounced in these times.

The letters my wife wrote to me in the course of her mission told me how you worked for her and revealed to me the extent and generosity of your projects for our wounded. Your hearts were open to our appeal; your country did not wait to come to our assistance. Powerful America wished to take under her protection our little people, tortured but always valiant.

My great sorrow does not permit me to reply as I wish I might to each one of you. Only to-day have I been able to measure,—thanks to the letter of your compatriot—Dr. Houghton—the extent of the gratitude I owe, to him first for having risked his life in trying to save that of my wife, and after that to you all for your devoted help in our common work.

Under the strain of my emotion, the sentiment of thankfulness is the only one to which at this moment, I am able to give expression. Permit me to do so with all my heart.

A. DEPAGE.

[The above is a translation of a letter sent by Dr. Depage to Dr. Richard H. Harte, of Philadelphia, with the request that it be published in acknowledgment of the many letters which he has received from America since the tragic death of Madame Depage. —EDITOR.]

BELGIAN PHYSICIANS' RELIEF FUND.

REPORT OF THE TREASURER OF THE COMMITTEE OF AMERICAN PHYSICIANS FOR THE AID OF THE BELGIAN PROFESSION FOR THE WEEK ENDING JUNE 26, 1915.

CONTRIBUTIONS.

Dr. Emery R. Hayhurst, Columbus, Ohio,	\$ 5.00

F. F. SIMPSON, M.D., *Treasurer*,
704S Jenkins Arcade Bldg.,
Pittsburg, Pa.

APPOINTMENTS.

NEW YORK POST-GRADUATE MEDICAL SCHOOL.—Dr. Edward J. MacNeil has been appointed director of the N. Y. Post-Graduate Medical School and Hospital in succession to Dr. Jonathan Wright, who has resigned. Dr. Morris S. Fine has been appointed adjunct professor of pathologic chemistry, Dr. Richard M. Taylor, adjunct professor of pathology and Dr. Paul J. Schule, lecturer in bacteriology.

BOOKS AND PAMPHLETS RECEIVED.

The Practical Medicine Series, Vol. III, The Eye, Ear, Nose and Throat. The Year Book Publishers.

Occupational Affections of the Skin, by R. Prosser White, M.D. Paul B. Hoeber, 1915.

What Every Mother Should Know, by Charles G. Kerley, M.D. Paul B. Hoeber, 1915.

War Surgery, by Edward DeLorme. Paul B. Hoeber, 1915.

RECENT DEATHS.

DR. AUBREY H. FITCH, who died on June 25 at Brighton, Mass., was born at Balie, N. S., on 1868. He received a degree in veterinary medicine from the University of Toronto and has practiced in Boston for many years. He is survived by his widow and by two daughters.

DR. SERAPH FRISSELL, who died of uremia on June 20 at Dalton, Mass., was born in Peru, on August 20, 1840. After graduating from Mt. Holyoke Seminary in 1869, she began the study of medicine in 1872 at the University of Michigan from which she received the degree of M.D. in 1875. In 1876 she settled at Pittsfield, Mass., and in 1884 removed to Springfield, where she continued active in the practise of her profession until a few years ago. In 1877 she was elected an honorary member of the Berkshire County Medical Society and in 1885 was admitted a member of The Massachusetts Medical Society and Hampden County Medical Society, but had not been a member of late years. During 1890 and 1891 she was resident physician and lecturer on physiology and hygiene at Mt. Holyoke College. She was unmarried.

DR. ALBERT WILLIAM HANCOCK, of Lawrence, Mass., was drowned while bathing at Salisbury Beach on June 18, 1915. He was born in Antigua, W. I., May 5, 1877, and was a graduate of the Harvard Medical School in the class of 1904. He was a fellow of the Massachusetts Medical Society, a member of the American Medical Association and of the Lawrence Medical Club. He is survived by his widow and one child.

DR. HOWARD MARSH, who died on June 25 at Cambridge, England, was born at Homersfield, Suffolk, England, in 1839. He was master of Downing College and professor of surgery at the University of Cambridge. He was a corresponding member of the New York Orthopedic Society, a Bradshaw lecturer in the Royal College of Surgeons of England and President of the Clinical Society of London. He was twice married and is survived by his second wife.

DR. FRANCIS TENN, who died on June 27 at St. Louis was born in 1866. He was instructor in gynecology at the medical department of the University of St. Louis.

DR. SAMUEL BALDWIN WARD, who died on June 3 at Albany, N. Y., was born in 1842. He received the degree of A.B. from Columbia University in 1861 and that of M.D. in 1864 from Georgetown University. In 1867 he became curator of the medical museum of Columbia University and professor of anatomy at the Woman's Medical College of the New York Infirmary. In 1870 he became professor of surgery at the same institution and in 1876, professor of surgical pathology at the Albany Medical College. In 1884 he became dean of this college and its professor of the theory and practise of medicine.

DR. CHARLES F. WOODRUFF, who died on June 13 at New Rochelle, N. Y., was born in 1850. He entered the United States Navy at a surgeon in 1880, but in 1887 resigned and entered the army with the same grade. He rose to the rank of lieutenant colonel and served as chief surgeon of brigade on the staff of General Merritt in the Philippine campaign. He also travelled extensively as sanitary inspector for the United States of foreign army posts. He was the author of "The Effect of Tropical Light on White Men" and "Expansion of the Races."

Address.

THE NEWER VIEWS OF "CANCER," AND THEIR PRESENT RELATION TO THE "RESPONSIBILITY" OF THE PRACTITIONER.*

BY EDWARD REYNOLDS, M.D., BOSTON.

THE last few years have witnessed the appearance of a widespread and general popular interest in "Cancer" as a public health question. Until the outbreak of the present war this movement was quite as active in the various European states, notably England and Germany, as in the United States and Japan. There is, in effect, a world-wide interest in this question. In the last few years there have sprung up in the United States alone nearly sixty organizations which are in one way or another devoting their labors to the solution of the cancer problem, and for the last two years there has been a national association, the American Society for the Control of Cancer, which has been endorsed by all the great medical associations of national scope and which is laboring to coördinate and consolidate the activities of all these many bodies towards the immediate reduction of the mortality from this disease by means of a generalized professional and popular campaign of education. Cancer has today the largest mortality of any disease of adult life, being in fact exceeded in its mortality only by the infantile diseases and

by that of tuberculosis at all ages, and if, as is now believed, by far the greater part of this mortality is readily preventable, there is good reason for the public interest in the subject.

While our knowledge of the essential nature of the malignant diseases is still imperfect, the work of the last few years has developed changes in our views of their natural history, which are already revolutionizing their treatment. The leaders of professional thought have now generally accepted the newer views of the natural history and preventability of malignant disease, but it is only lately that their conviction has crystallized into the active teaching of these views which is now taking so prominent a place in both the professional and public press.

The laity are awakening to a widespread interest in them as is shown by the eagerness with which the daily newspapers are publishing "Cancer" articles, both well inspired and the reverse.

The profession are proving singularly apathetic to the movement, perhaps because it is always easier to impress a new point of view upon those who have had no previous acquaintance with the subject than upon the better educated who have long been adherents of an opposite point of view: but from whatever cause this apathy may arise, recent studies by many authorities have made it plain that the great mass of the profession have not abandoned the antiquated, nor assimilated the more modern, views of the natural history, prognosis, or curability of malignant disease, and have developed further the very curious fact that this backwardness is almost, if not quite, as prevalent among promi-

* Prepared for delivery at the annual meeting of The Massachusetts Medical Society on June 9, 1915.

nent metropolitan medical practitioners as in the more remote districts. That the public should be accepting an advance more readily than the profession is far from a safe position for either the practitioner or his patients.

This paper has, then, two objects: an attempt to set forth in concise form the accepted points in the newer knowledge of malignant disease, and, incidentally to attempt to show, both by general discussion and by quotations from personal experience, that although these principles have been so universally accepted by the leaders of both pathological and surgical thought that they may today be regarded as assured, they, nevertheless, have not been as yet so generally assimilated by the great mass of the profession that a failure to have accepted them can be as yet considered as constituting that lack of the "common knowledge of the profession" which some of the laity now seem in danger of believing that it is.

The essential facts in our most recent view of the malignant diseases are, then:—

That they are at first strictly localized and during this localized stage are curable.

That there is no sharp line of demarcation between the benign and malignant new growths or ulcerations, but that the malignant often, if not usually, follow the benign and originate in them.

That while it is perhaps true that only a minority of even long continued benign neoplasms or ulcerations ever undergo a malignant change, such an occurrence is, nevertheless, so far frequent that every continued neoplasm or ulceration should be considered so far potentially malignant as to demand serious consideration.

That a heavy burden of responsibility always rests on any physician who declares that any new growth or ulceration which is brought to his attention is benign and therefore unimportant.

The most fundamental point in these principles (that the malignant growths and ulcerations are frequently secondary consequences of benign lesions and that consequently the benign can seldom be safely considered permanently benign) was on the point of realization fifty years ago. In support of this the reader may be referred, among other books, to Gross' once well known volume on "Tumors of the Mammary Gland," in which the clinical evidence for the transmutation of the benign into the malignant is quoted from a long line of his predecessors. The evidence was even then so overwhelming that this view would undoubtedly have shortly become the common property of the profession if the opposite view had not been adopted with great vehemence by a number of eminent pathologists. We can now perceive that these gentlemen were prejudiced in favor of the microscope and against anything but laboratory evidence. The sneering attitude which they and their successors adopted towards the opposing views unfortunately, for the time, carried the day, and as a result all the profession now in practice, with the exception of a few of the very youngest, were educated to a

firm belief that the benign, if once correctly diagnosed as such, must remain benign forever. This most unfortunate error has cost the lives of countless thousands and persists in the minds of the great mass of the profession even today, when there is perhaps no pathologist of authority who still adheres to it, and when the clinical evidence to the contrary has become overwhelming. Now that the contrary view has been for some years universally accepted by the surgical side of the profession, and especially since the laity is becoming generally imbued with it, it is of the utmost importance that its existence, as at least a probability, should be brought to the attention of every practicing physician, for his judgment upon it.

That the great mass of the profession still adhere to what all but the youngest were taught in their student days, i.e. to a belief that benign and malignant neoplasms and ulcerations are totally distinct phenomena, that they are to be distinguished from each other by a carefully outlined differential diagnosis, and that the benign cases will remain permanently benign and may therefore be neglected, has been of late repeatedly demonstrated. Among other evidence we may quote the following:—

The very active and excellent Cancer Commission of the Pennsylvania Medical Society collected statistics on 400 operative cases of malignant growths with the result of showing that in these cases the patient's physician had known of the conditions present, in superficial cancers for an average of one year, and in deep-seated cancers for an average of thirteen months before any treatment was undertaken. The commission remarks in its report that these results when tabulated were "somewhat startling."

An almost exactly similar result was obtained by a recent tabulation of 65 patients made in New York, and other similar statements have been made by almost every surgeon who has lately written on the subject. It is curious, too, that most of them remark that the failures to advise judiciously prompt action occur almost as frequently in metropolitan circles as in the remote districts where backwardness would seem more excusable. If this last statement be true, as I think it is, it is another point in favor of the belief that a failure to have as yet absorbed the modern views which may now be stated as accepted knowledge among specialists cannot as yet be held to constitute liability for "Failure to possess the common knowledge of the profession as a whole."

A recent review of personal records makes it seem, however, as though this were not the last word which should be written upon the subject. This review has indeed made it most clear that in this section of the country at least the degree to which recent advances have permeated the mass of the profession varies greatly, as between the several localities in which cancer is most frequent, and after careful consideration it has seemed that the most clear and comprehensive

way in which the subject can be presented is by a consideration of the malignant diseases under each of the four groups of organs in which they most commonly occur.

In a single brief article it is, of course, impossible to discuss the symptoms, diagnosis and curability of the malignant diseases in the many situations in which they occur less frequently. This paper will then be limited to their discussion under the heads of: Cancer of the Breast, Cancer of the Uterus, Cancer of the Digestive Organs, and the Cancer of the External Surface and Orifices of the Body.

The method adopted will be the presentation in brief form, under each of these classes, of the general principles which should govern the management of cancer in that situation, and the illustration of these principles by cases selected from personal experience, in so far as the extent of that experience renders this possible.

It must be promised further that the word cancer is here used in its popular sense and as a more convenient term than "malignant disease."

The cases used in illustration have been selected to show, both the very general failure of the profession to as yet grasp the fundamental points of our newer knowledge, and at the same time the principles which should govern their management. It will then be obvious that the names both of the patients and of the professional gentlemen by whom these patients were first seen must necessarily be omitted. They will, therefore, be reported only under the case numbers of the writer's clinical records.

BENIGN AND MALIGNANT TUMORS OF THE BREAST.

The breast is a locality in which carcinoma is extremely frequent. It is, furthermore, a situation in which early action is extremely important since secondary invasions into the axilla and sub-clavicular space, *i.e.* generalization of the disease and an unfavorable prognosis, occur very soon after the appearance of a malignant change in the original nodule.

It is perhaps the locality of all others in which disastrous delay is at present most often practised, and this probably because it is, of all localities, that in which the differential diagnosis between the benign and malignant growths had been in former days most carefully worked out and most generally taught. It is really that in which there is, in fact, least distinction between the benign and the malignant, and in which the origination of the malignant growths in masses which were evidently benign at the start is today most apparent.

It is, too, one of the localities in which the discovery of the new growths in their initial and harmless stage is most easy, and in which their removal while still benign is most easily effected without mutilation, and by trifling operations. It is, moreover, perhaps of all others, the locality in which the difference between the trifling

nature of these operations for the removal of a small mass, and the disfigurement of the extensive operations for the removal of established carcinoma is most distinct and apparent.

The general principles which should govern the management of new growths of the breast are:—

That all perceptible lumps in the breast, except the acute inflammatory masses in the nursing breast, should be regarded as potential carcinoma.

That all lumps in the breast which are evidently persistent should be at once removed, no matter how small they are or how evidently benign they may appear.

That in cases in which the patient is seen so soon after her detection of an apparently insignificant lump that it may be necessary to delay a little in order that the physician may assure himself of the certain presence and actual persistence of the mass, the patient should be seen at very short intervals, and the delay should be counted at most by weeks and not by months.

That he who delays more than a very few weeks before acting himself, or seeking expert advice, in the case of small and apparently, evidently benign new growths, or who delays at all in the case of larger and doubtful growths takes upon himself a responsibility which men of wide experience would not endorse.

Mammary lumps of benign appearance are sometimes unexpectedly malignant.

CASE 1. Private Records, Series B. 2933. A married woman of 48 was sent by a leading physician in another city, who stated in sending her that he had found a large uterine tumor, probably fibroids, which in his opinion demanded removal; that he had also found a moderate sized mass of apparently benign character in the left breast which he thought should also be removed; but that he thought the questions,—which tumor was the more pressing, whether either of them might be temporized with, and whether the patient could withstand the performance of both operations at one sitting, were intricate and grave. The latter course was decided upon. The fibroids were removed by hysterectomy in the presence of Dr. Wm. F. Whitney, who on section pronounced them to contain no malignant tissue. The left breast was the site of a mass about the size of a two-ounce bottle, movable, unattached to the skin, uniform in shape, and in short presenting every evidence of a benign nature. A Warren incision outside the breast was made in the expectation that the growth could be removed without disturbing the remainder of the breast and without mutilation. The greater portion of the tumor had been removed in this way when its upper portion proved to be far less movable than had been supposed and on submission of the specimen to Dr. Whitney it was found to contain two carcinomatous nodules of small size situated at distinct and well separated points of a hard, fibrous, and otherwise benign tumor. The necessary extension of incisions was at once made, the breast and pectoral muscles removed and the axilla and sub-clavicular spaces cleaned out. One axillary gland was enlarged, but

on section showed no evidence of new growth. After a lapse of nearly seven years there has been no recurrence and the patient is in the best of condition. She undoubtedly owes her life to an intelligent and progressive family physician, who urged her to an immediate operation within a few days of his first discovery of the condition. With two nodules of actual carcinoma, and an axillary gland already enlarged, it is probable that the loss of but a very short time would have put this patient in the hopeless class.

The case is quoted as an excellent illustration of the necessity for early operation in apparently merely benign tumors, and of the importance of having a pathologist present at the operation, for I think no sane surgeon would have added an extensive radical operation for carcinoma of the breast to a complete hysterectomy, without an actual microscopical demonstration of the presence of carcinoma in the breast during the progress of the operation. It is also an excellent illustration of the importance of prompt action on the part of the general practitioner.

A further general principle which for the sake of clearness was omitted on a former page, but which applies to all cases of malignant disease may appropriately be inserted here. Recent experience and statistics have shown clearly that the percentage of subsequent immunity is greatest when the microscopical examination of a specimen and the radical operation (if the disease is malignant) are both executed at the same sitting. It has been shown most clearly by statistical study that to permit an interval between the removal of a growth for microscopical examination and a subsequent radical operation increases the percentage of recurrence substantially.

It should, therefore, be a general principle that all operations for the removal of a portion of a doubtful growth should be done in the presence of a pathologist and with the patient prepared for a radical operation if his report is unfavorable.

Delay may convert an undoubtedly benign tumor of the breast into a most malignant growth.

CASE 2. Private Records, Series B, 3963. An unmarried woman of 36 was sent in by a leading medical practitioner of another city, a gentleman whom I have known for many years, whom I regard as one of the best general medical practitioners in Massachusetts, and whom I have seen exhibit in several other cases great clinical acumen and a most progressive spirit. He is in no sense a backward practitioner. He had known and attended this patient from her childhood; and when, a year and a half before I saw her, she came to him in a state of great agitation, stating that for a number of years she had known that her left breast was enlarged, and that she had recently discovered a lump, he made a careful and conscientious examination and assured her that the growth was benign and that she need not worry. His differential diagnosis was entirely justified by the characteristics

of the tumor, if such a diagnosis is ever safe. Under all the rules of practice which he had been taught and had applied all his life the position he assumed was the right one, but it happened that in his busy life and in spite of his progressive spirit and wide reading he, a medical practitioner, had not happened upon the latest surgical dicta about cancer of the breast. He saw her from time to time, and when at the end of a year it was evident that the growth was enlarging he told her that it would probably be necessary to remove it at some time, but that there was no hurry. He had not happened upon our latest advance of knowledge that a tumor once benign is not necessarily always benign. After a year and a half of observation he advised operation. There was at this time a diffuse mass centralized below the nipple and extending through a considerable portion of a large breast. For two or three months the patient had noticed a very slight serous discharge from the nipple which had from its start been slightly orange colored, and within the last few days had become slightly bloody. Firm pressure on the mass produced an increased flow of this fluid. It was nowhere adherent to the skin and appeared freely movable in all directions. It was diagnosed as a multiple cystic mass which had of late taken on a doubtful character. There was no evidence of enlargement in the axilla. A diagnostic incision from the nipple to the outer edge of the breast, made in the presence of Dr. Whitney, confirmed this diagnosis, and made it evident that small cysts would be found throughout the breast. The whole breast was removed and was submitted to Dr. Whitney. The operation was suspended while he made a prolonged examination of the specimen. In spite of his enormous experience in this class of cases, and for the first time in the writer's long collaboration with him, he refused to give a positive opinion, but recommended that nothing more should be done, his belief being strong that the growth was not malignant, and that it was for the patient's interests to take the additional risk of recurrence which would be involved in the postponement of the remainder of the operation for a few days, in case a pathological examination at leisure showed some malignant tissue, rather than to lose her pectoral muscles and axillary tissues at this sitting. After hardening the specimen and making serial sections Dr. Whitney found a nodule of carcinoma, and three days later at a secondary operation the pectoral muscles were removed with the axillary and sub-clavicular glands. The axillary glands proved to be extensively carcinomatous. The case is a very recent one and the patient is in good condition, but the prognosis is not good.

When a practitioner of the class of this patient's family attendant takes the course that he did, not carelessly or without thought, but after the exercise of his best efforts in a case in which he was deeply interested, it is evident that the day has not yet come when our recent advances have become the common property of the profession, or when the general practitioner can be held liable for lack of common care and knowledge if he counsels delay in the management of a case of benign tumor of the breast such as this case undoubtedly was when it was first seen; yet here is a case in which the patient was subjected to extensive mutilation and grave risk for the future, both of which might easily have been

avoided had she been made the subject of a minor operation at the time when she first brought the lump to the attention of her physician. It is further quoted as a case which illustrates most effectively the development of malignancy in a growth which was plainly cystic, was long existent, and therefore had been undoubtedly benign at the start.

The axillary glands in this case were extensively involved, and it is not probable that the three days' delay between the biopsy and the second operation was of any serious importance in this case, yet it is evident that as the case turned out it would have been better for the patient if the complete extirpation had been done at the first sitting. That the malignant tissue was so inconspicuous as to escape the observation of an unusually experienced pathologist until after prolonged search, makes it exceptionally striking as a transition case.

Any definite chronic lump in a breast should be removed while that is possible by a non-mutilating operation.

CASE 3. Private Records, Series B, 3333. Married woman, 41 years old, childless. Family history of repeated carcinoma. When first seen was complaining of abdominal discomfort and tenderness, with dysmenorrhea, and some pain in left breast during catamenia. All these symptoms were of some years' duration. On examination there was a probable small right tubo-ovarian enlargement, and a doubtful lump in the left breast. Under minor treatment improved considerably, and was recommended to return at short intervals for observation, but eight months later reported recurrence of catamenial discomfort with increased flow, and several inter-catamenial attacks of pain and flowing. Left breast more painful than before during catamenia. On examination right tube certainly quiescent, uterus certainly not enlarged, foul cervical leucorrhea, and a small but now for the first time distinct lump just outside the left nipple. Recommended dilatation and curettage and excision of mammary lump. At operation a week later the cervical canal was found so nearly impervious and the substance of the cervix so cirrhotic and brittle that an amputation of the cervix was judged safer, and likely to be more beneficial, than a dilatation—it was followed by a curettage. The lump in the breast being outside and below the nipple, was exposed by a small radiating incision and proved to be somewhat diffuse and ill outlined. A small pie-shaped section of the breast was removed. Careful palpation through the incision showing the rest of the breast to be free from trouble, and Dr. Whitney pronouncing the specimen non-malignant, the incision was closed. The subsequent microscopic report upon the breast was glandular proliferation with dilated ducts and acini. Diagnosis: diffuse glandular hypertrophy.

This patient's family history showed several instances of death from carcinoma. The removal of an abnormal cervix by a vaginal operation which probably involved less risk than the dilatation of a brittle cervix, not only removed abnormal tissue, but provided the permanently

good uterine drainage which will give her the best possible chance for the disappearance of one of those chronic irritations which it is always well to dispel. The new growth of the breast was distinctly benign but was of the class of diffuse, proliferative, benign new growths which, when they appear during the forties, are extremely well worth removal. Neither operation involved risk or disfigurement other than the linear scar in the breast. More time after the actual appearance of the mammary lump might have been permissible for observation, but the conditions were definite, and the loss of time, a week in bed and a week of convalescence, seems fully justified for prophylaxis.

The apparent initial delay of eight months was due to the two facts that at the first visit the evidence of the presence of a mammary lump was of doubtful force and that the patient failed to report in one month as she was directed to do.

It may be noted that when these small lumps in the breast are in the external or outer quadrants a radial incision is usually preferable, but that when they are so situated that the radial incision might be visible in evening dress they may be removed without disfigurement by the Warren operation, in which the incision follows the lower and outer edge of the breast and the mamma is separated from its underlying fascia and turned upward and inward, after which a benign mass in any part of the breast can be removed without further incision through the skin, the operation being in fact no more severe to the patient than that done through a linear incision.

CANCER OF THE UTERUS.

Uterine cancer occurs in two forms which have quite different characteristics both pathologically and clinically. The squamous called cancer of the cervix originates, as its name implies, in the cervical portion of the organ and remains limited to the cervix throughout the earlier stages of the disease. It is ulcerative and excavative in character and undergoes extension through the lymphatics of the broad ligaments extremely early in its course. After this disease has once become definitely malignant the most radical operations yield comparatively few cures; on the other hand, while almost incurable when once established, it is yet extremely susceptible of prevention. It probably originates always in or about superficial ulcerations or erosions of the vaginal portion, and if all such lesions occurring in women over thirty-five or forty were efficiently treated while they are in this stage, we should have practically no cancer of the cervix. The main initial symptom, and perhaps the only distinctive symptom of this affection, during the benign, or as it is often called, pre-cancerous, stage is the existence of a leucorrhea, usually irritating in character and sometimes a little streaked with blood. This symptom is, of course, not pathognomonic of

cancer; it is in fact characteristic of all the irritative conditions of the cervix, the great majority of which would not develop malignancy; but the all important fact is that though all leucorrhæas originating in middle life, are not the result of cancer, yet nevertheless all, or almost all, cancers of the cervix are preceded by such leucorrhæas, and could be prevented from occurring by efficient treatment of those leucorrhæas.

At the risk of repetition, we may then say again that if all such leucorrhæas beginning in middle life were efficiently treated there would be practically no cancers of the cervix. Every case which presents this symptom should be carefully examined both bimanually and through a speculum, and the source of the leucorrhæa accurately determined. In many cases the ulceration or erosion can be healed by minor treatment and in some cases will remain permanently cured, with consequent disappearance of the leucorrhæa, but in a larger number of cases, and in all the more important cases, the trouble will recur within a short time after its relief by minor treatment. In these cases permanent relief can, however, be obtained by the appropriate plastic, which may be in one case the Emmet operation for lacerated cervix, in another the equally trifling operation of an amputation of the vaginal cervix, or in a third the enlargement of a narrowed external os and the institution of adequate cervical drainage by a Pozzi or Dudley dissection. The relief to general health and discomfort afforded by these now trifling procedures is in most cases sufficient by itself to warrant their performance, if minor treatment fails of a permanent result; and they are far more than warranted by their efficient prophylaxis of cervical cancer.

Cancer of the uterine body presents a very different picture. It begins in the mucous membrane of the uterine body, usually as an adenoma, and often preceded by long existing glandular hypertrophy. It progresses somewhat slowly through the stage of adeno-carcinoma into fully developed cancer, but it tends to remain strictly localized within the uterus until a late stage in the disease, when it is usually disseminated by the protrusion and perforation of some portion of the disease through the peritoneum covering the uterus; after which secondary new growths spring up at separated spots all over the peritoneum, probably by the dissemination of cancer cells throughout the peritoneal fluid and their implantation and growth at spots determined by chance.

Cancer of the body gives a good prognosis after total hysterectomy throughout all the earlier part of its course, and a fairly good prognosis after the same operation, until it actually escapes from the uterus and becomes disseminated. Its onset is usually attended by the appearance in the earliest stages of a flow which is at first intermittent and scanty, later continuous and often large in amount, but which is throughout sero-sanguineous, until as the dis-

ease becomes extensive it usually becomes definitely sanguineous. When this discharge is present in typical form it is practically pathognomonic of adeno-carcinoma of the body. Unfortunately it is not always distinctive. As a result, no doubt, of some peculiarity in the localization or character of the growth there are not a few cases in which the character of the discharge is sanguineous from the start. Frank flowing in a woman of middle age must, therefore, be regarded as also suspicious.

The adeno-sarcomata of the uterine body, though much less common, have a very similar clinical history and may be included here under the general title of malignant disease or "cancer" of the body.

There is a common superstition which is widely prevalent among the laity and too common in the profession, to the effect that increased flowing at the menstrual period is a characteristic of the menopause and is harmless. There is, perhaps, no false belief connected with uterine disease which works more widespread disaster than this. The leading characteristic of the years which precede the climacteric in a woman with normal organs is a decrease in the amount of the catamenia. Any inter-menstrual flowing at this time of life is almost certainly the result of some neoplastic condition (including here the conditions usually grouped together under glandular hypertrophy of the mucous membrane); and though an increased flow at the normal time is not always neoplastic and may even disappear spontaneously, it is always the product of some abnormality in the organs, and is so often the first symptom of a new growth that it should always be regarded as a danger signal which demands attention and a careful diagnosis of its cause.

One other form of malignant disease must be mentioned here as being practically, if not strictly, uterine before we can summarize the general principles which should guide the practitioner in his management of the early stages of malignant disease of the uterus. A considerable proportion (not less than 20%) of those fibroids which first appear during middle life or which persist through the pre-climacteric or climacteric period undergo, sooner or later, a malignant degeneration, usually sarcomatous. Such fibroids should, therefore, be removed while still innocent.

The importance of increased flowing during middle life, and more especially of any recurrence of flowing after the menopause has been so far hammered into the profession for now so long a period of years, that, in this section of the country at least, the neglected cases which are still occasionally seen are usually the fault of the patient rather than of her family practitioner, the comparatively few cases where the family attendant has delayed action too long being usually cases of cervical rather than corporeal cancer. Too many general practitioners still fail to realize that since malignant disease habit-

ually occurs either within the substance of benign tumors or about chronic inflammations or irritations, no erosion or ulceration of the cervix which is seen in a woman of middle age can be safely pronounced benign and unimportant.

Every member of the profession ought to realize that an ulceration of the cervix which is plainly benign at the time he sees it may, nevertheless, become malignant in time, and should for this reason, if for no other, be treated and treated to a permanent cure, as surely as it is discovered. The comparative backwardness of the profession on this point in uterine cancer is undoubtedly due to the fact that its full realization has come to us only lately. It is but a comparatively few years since gynecologists in general have come to an active recognition of the principle that a benign irritation of the cervix cannot be trusted to remain permanently benign in a woman of middle age.

The general principles which should govern our management of incipient cancers of the uterus are, then:—

That while every irritating or blood streaked leucorrhea in women in middle life is not necessarily malignant, every such leucorrhea is so far suspicious of malignancy that it must be taken seriously, and demands an examination which should be pushed to the point of showing a satisfactory cause for the leucorrhea.

That every erosion or ulceration of the cervix in a middle aged woman should be regarded as a possible source of cancer and treated for the prophylaxis of cancer.

That the milder lesions of this character may be treated by minor means, but that all the more severe of these lesions, and those milder ones which recur after minor treatment, should be treated by excision of the inflamed tissue.

That this should always be done in the presence of a pathologist, and with the patient prepared for radical operation if malignant tissue is found.

That all cases of marked increase of the catamenia during middle life should be regarded as suspicious, all cases of inter-menstrual flowing or of recurrence of flow after the menopause as highly suspicious, and all cases of intermittent sero-sanguineous flow as pathognomonic of cancer of the uterus.

That these symptoms are rendered more significant by the coincident existence of enlargement of the uterus, but are not necessarily negatived by its absence.

That any such flowing demands careful curettage in the presence of a competent pathologist and with the patient prepared for hysterectomy in case an examination of the curettings shows malignancy.

That a negative result from the examination of the curettage relieves the operator of the necessity of performing a hysterectomy at that sitting, but does not warrant a positive or permanent diagnosis of a benign source of origin for

the flowing. This point is an important one and will be illustrated by cases.

That all fibroids or polypi occurring or persisting during middle life should be promptly and radically removed.

Benign growths of the uterus do not necessarily remain benign.

CASE 4. Private Records, Series B. 3356. A widow of 61 whose sister had died in this patient's house a little while before of a cancer which was recurrent six months after a hysterectomy, presented a small polyp protruding from the os. Under ether the cervix was split bilaterally to the internal os, when several additional polypi were seen hanging from long stalks, but evidently originating within the fundus. The internal os was dilated and the uterus very thoroughly curetted. The polypi and curettings were submitted to Dr. Wm. F. Whitney, who pronounced them wholly non-malignant. The patient was, however, urged to report every six months, which she did for about two years in normal condition. Three years and a half after the removal of the polypi she again had a slight show, and at once reported. The uterus seemed slightly enlarged. She was curetted in the presence of Dr. Whitney. Very little material was obtained and Dr. Whitney pronounced this negative, but the uterus was four inches deep. This fact in a woman of 65 with recurrent flowing, and whose uterus was known to have been small three years before seemed highly suspicious, and was thought to warrant an exploratory abdominal incision. Note her prolonged exposure to another case. This at once showed an enlarged uterus of soft and suspicious consistency and containing a number of small fibroids. It was removed by hysterectomy and was found by Dr. Whitney to be in the stage of infiltrating adenoma. There has been, of course, no recurrence.

The technical difficulties involved in procuring a complete examination of the mucosa by curettage and the examination of the fragments are such that a negative result is always unreliable. If the symptoms persist the curettage should be promptly repeated.

CASE 5. Private Records, Series B. 3409. A sterile woman of 53 had noticed for two years a profuse leucorrhea, which had been lately increasing in quantity and had become bloody. Upon examination the uterus was not enlarged, but a foul and bloody leucorrhea could be seen to escape from the os. Curettage was recommended, but she was not seen again for three and a half years, when she reported that she had been curetted and the curettings declared negative; that the leucorrhea had not improved, had gradually become watery and slightly colored, but of late had been bloody. She said that the curettings having shown the case to be non-malignant, neither she nor her attendant had been worried, but that the discharge was now becoming annoying in quantity. On examination the uterus was found much enlarged and the discharge pathognomonic. Curettage brought away adeno-carcinomatous material and a hysterectomy removed an adeno-carcinomatous uterus, in which, however, the growth had fortunately not yet penetrated the wall. The case is somewhat recent but the prognosis is fairly good.

CANCER OF THE DIGESTIVE ORGANS.

Cancers of the digestive organs form an important and on the whole unfavorable group.

Cancers of the great digestive glands, the liver and pancreas, fortunately form a small proportion of this group as they can rarely at present be diagnosed while in a condition which offers any great hope.

The more common seats of this group of cancer are in the stomach and large intestine. The great majority of all cancers originate about chronic ulcers, and if all chronic ulcers of the stomach were promptly healed or excised the malignant diseases of the stomach would be greatly decreased in frequency, if not done away with. Not all ulcers can be healed without operation, and while duodenostomy for the relief of gastric irritation and the excision of a portion of the stomach for the removal of a benign ulcer are no longer operations which carry a large mortality, they are still far from trifling operations; they certainly cannot today be placed in the class with removal of small lumps in the breast as trifling procedures which should be performed as a routine for the prophylaxis of cancer. Each case of this character must be treated on an individual basis, but the general principle which should govern their management is undoubted; if every case of gastric indigestion in a middle aged person which proves to be annoyingly persistent and resists ordinary methods of treatment were regarded as suspicious of cancer and subjected to diagnosis by the most careful methods of physical examination, including analysis of the stomach contents and the bismuth x-ray used with a series of instantaneous exposures, there would be an immediate reduction in the number of deaths from cancer of the stomach. These methods of examination are as yet far from perfected. They require the use of elaborate and expensive apparatus, and in special such x-ray plates as are demanded for this purpose cannot be obtained by the ordinary office outfit, or indeed by any one but an expert Roentgenologist. Their interpretation is difficult and usually demands consultation between medical and surgical experts. Each case is a problem by itself and a problem for serious study. Probably all that can be demanded of the general practitioner today is that he should realize the possibility that any case of persistent indigestion in a middle aged person, especially if attended by loss of weight and change of color, may often mean the beginning of what may in the end become a malignant process; and that the patient has a right to be warned of this and to take advantage of the excellent chance of escape which is afforded by such expert study of the case in the early stages.

Cancer of the intestine is most common in the lower intestine, and is there most common in the sigmoid and rectum. In this last situation there is, under modern methods, a good chance of its detection while in the early stages. In the other

parts of the bowel it is rarely detected before it has become definitely malignant, and but seldom while it is susceptible of successful radical removal.

The early symptoms of a new growth in any part of the colon are persistent constipation with consequent indigestion and brownish discoloration of the skin, usually some loss of weight, and as a rule sense of weight in the pelvis and some straining at stool.

Lack of space must prevent discussion here of most of the somewhat intricate problems involved in the diagnosis and surgical treatment of cancer of the colon in its several situations, and that of the lower portion only will be selected for illustration.

Cathartics and enemata do not produce satisfactory results, and though in cancer of the upper part of even this region the habitual motions often consist of large well formed feces, yet after the use of cathartics, *i.e.*, after the rectum is emptied and the feces begin to come down from above, ribbon feces may often be detected. Slight rectal bleeding or streaking of the feces, with blood may be observed in the early stages, either as the result of hemorrhoids secondary to the constipation and indigestion, or from irritation and bleeding of the mucous membrane at the point of obstruction.

It will be observed that no one of these symptoms is pathognomonic of a new growth. The whole symptom-complex is merely that of moderate obstruction in the lower bowel, and may be due to any one of many causes.

An actual differential diagnosis between obstruction due to a malignant growth and one which is the product of some other mechanical cause can rarely be made by any method, and the differential diagnosis between the benign and malignant new growths can never be established in the early stages. The utmost that we can expect is the detection of an actual mechanical obstruction in this region; when the strong probability which always exists in middle aged people that such an obstruction is due to actual or potential malignancy must always be an element in the determination of treatment. In some few cases after thorough emptying of the bowel by the persistent use of cathartics and enemata, it may be possible to distinguish a mass by combined recto-abdominal, or in women recto-vaginal-abdominal palpation under anesthesia, but this is rarely possible in the early stages. It is, moreover, a safe general principle that benign new growths of the intestines usually, and persistent localized inflammations with thickening of the walls amounting to obstruction frequently, become in time malignant if left undisturbed.

The diagnosis of actual mechanical obstruction with or without a probability that the obstruction is due to a new growth of some nature can usually be established by the use of the bismuth x-ray and can frequently be confirmed by the proctoscope, which under modern technic

can often be made to explore successfully the whole of the sigmoid, and in some cases the descending colon.

The conditions of these cases are such that the problem involved is an essentially surgical one, yet the hopeful part of the surgeon's problem can only arrive when the patient or the original attendant has recognized the possibilities early, and the necessity of the patient's taking the decision in the case must usually make it necessary that the family attendant should take his full share in the discussion of the possibilities, hence it is important that the general practitioner should be familiar with their general outline.

The surgical problem presented by new growths of the rectum and sigmoid, whether they are detected in the benign or malignant stage, is never an easy one for either the patient or the surgeon. In a very large proportion even of the ultimately successful cases, the operation involves at least a temporary colotomy and its subsequent closure. In most new growths, and in all malignant growths, of the rectum or lower sigmoid the operation is best done in two stages, and if the growth is in the rectum or extreme lower end of the sigmoid it can but seldom promise any better ultimate result than a permanent colotomy with the discharge of feces through an artificial anus in the abdominal wall. Nothing but the dreadful suffering which attends death from cancer of the rectum can be worse than the condition of the patient who has a permanent artificial anus and the possibility of a recurrence of the disease below.

Even in the exceptional cases in which a benign or early malignant growth of the sigmoid is so situated that it can safely be removed by resection, and that the divided ends of the intestine can be brought together without undue tension, the operation is one which involves a large mortality. The death from cancer of the rectum or sigmoid is, however, one of such great suffering, and the last stages of life so frequently demand the formation of an artificial anus for comparative euthanasia that the risks involved in a resection are well worth taking whenever that operation is possible, and an exploratory abdominal incision on the chance that the growth may be removable, and the possibility that it may be removable without a permanent artificial anus, is probably wise in any case in which a tumor of the rectum, or more especially of the sigmoid, has been detected.

In the writer's opinion the general principle of the management of such cases should be that the patient should be given a full explanation of all the circumstances of the case with the arguments for and against operation fairly and lucidly set forth, and should be allowed to make his own decision. No other course can safe-

guard the patient and his family from unavailing regrets or the surgeon from sharp criticism.

CASE 6. Private Records, Series B. 3781. A single woman 38 years old. Had been operated upon eleven months before by a first class metropolitan surgeon whom she had consulted for dysmenorrhea, difficult defecation, and bearing down pain in the pelvis. He removed an ovarian cyst only to discover a new growth in the rectum. He excised a section of this growth and submitted it to a competent pathologist, who pronounced it benign. The patient and her family gathered from him the impression that the growth was harmless and would require no treatment. The patient's pain was not relieved by the operation but increased in severity. The family, in consequence of the impression that they had gathered from the surgeon, believed her pain to be hysterical and insisted that if she would pay no attention to it it would disappear. She was sent to a neurologist, who after a time became convinced that the pain was organic in origin and recommended another opinion. The touch revealed a large retro-uterine mass compressing the rectum. The proctoscope and the x-ray added confirmatory evidence of its rectal situation, extent, and probable malignant character. The patient's pain was evidently unendurable, and even when the desperate nature which would now characterize any operative attempt to relieve her had been fully explained to her, she demanded operation, on the ground that the barest chance of relief was worth anything that she might have to go through, and that death from operation was preferable to her existing pain; her only stipulations being that the operation should be the most radical possible and that she was willing to take any and all risks. An incision demonstrated the absolute impossibility of any removal of the growth, but a portion was excised and pronounced carcinomatous, and a colotomy was done for the relief of the incessant rectal tenesmus. Fortunately for the patient she failed rapidly after the operation and died in forty-eight hours.

From the rectal situation of this growth it is probable that even while it was small and benign an operation for its removal would have involved the establishment of a permanent artificial anus, and the surgeon who found an operation for the removal of an ovarian cyst complicated by the presence of such a tumor of the rectum, would probably have been unjustified in subjecting the patient to the great risk and grave mutilation involved in so extensive an operation without giving her a chance to decide upon it herself in advance: but had she been informed of the probability that the persistence of this small growth in her rectum would probably in the end expose her to the suffering involved in a death from cancer of the rectum, she would certainly have been carefully watched, and would have made up her mind at leisure upon the choice between the two alternatives offered, at a time when the radical operation would have offered her at least a chance of life, and of relief from suffering.

Her family would have been spared much self reproach for having urged upon her that her undoubtedly intense pain was hysterical. The surgeon concerned would have escaped very severe criticism.

Where the tumor can still be regarded as fairly benign the possibility of complete functional cure, as opposed to the inevitable suffering which results from the development of malignancy, should never be ignored in making the decision.

CASE 7. Private Records, Series B. 3926. A single woman of 60. Had had occasional abdominal pain for seven years. Hemorrhoids for three years and of late urinary frequency. Palpation of the abdomen developed the presence of an enormous amount of feces in the descending colon and sigmoid, rendering further examination useless. A week of hospital treatment with catharsis and enemata emptied the colon, with the production of unusually large quantities of feces. Examination under gas developed the presence of a small nodular mass, movable in the pelvis and probably intestinal in situation. The proctoscope was arrested at a spot which was believed to be in the lower sigmoid and to represent a narrowing of the lumen of the gut with somewhat reddened mucous membrane. The patient had lost weight and flesh, and the skin showed marked brownish discoloration, but cachexia was not marked and the constitutional condition was not worse than could be explained by constipation and the retention of feces. The diagnosis was neoplasm of the sigmoid, character uncertain. An abdominal incision showed a new growth involving about eight inches of the gut at about the junction of the sigmoid and rectum. Careful search showed no secondary nodules. The affected portion of the gut was removed and submitted to Dr. Whitney, who pronounced that it was benign and consisted of a portion of gut with much contracted lumen, and its walls thickened by numerous small diverticula surrounded by inflammatory induration. The conditions were extremely unfavorable for an end-to-end anastomosis and the ends of gut were too short to permit of a lateral anastomosis without unsafe tension. It was, however, possible to bring both ends of gut into the abdominal wound and fasten them there with stitches and forceps. The patient made a prompt convalescence, the resulting spur was divided by forcipressure, and after somewhat prolonged and unsuccessful attempts at closure of the abdominal fistula by granulation, the abdomen was re-opened and both ends of gut having become much elongated, and moreover extensively adherent to each other as the result of the forcipressure, closure of the remaining portions of their walls by suture proved easy and to leave a good lumen. The subsequent progress of the patient was satisfactory and her prognosis is of the best.

CANCER OF THE ORIFICES AND EXTERNAL SURFACE OF THE BODY.

Such lesions as cancer of the tongue, cheeks and lip illustrate well the origin of malignant disease in chronic irritations.

Every one knows the chronic cankers of the tongue and cheek which result from the digestive action of the saliva upon some slight abrasion of the mucous membrane. Almost every individual has experienced their presence. They are usually of but a few days' duration and are harmless; yet it has been for long well established that cancers of the tongue and cheek originate almost invariably in such simple ulcers (common canker), which instead of disappearing spontaneously in a few days as they should do, are kept open for weeks or months by the unrelieved presence of the rotten or ragged teeth or other mechanical irritation which originally produced them.

Cancer of the lower lip has been long and classically recognized as the product of the irritation caused by the long continued irritation of a hot or rough pipe stem against a given spot on the lower lip in inveterate smokers. Cancer of the larynx (cigarette cancer) is the product of continued irritation of the vocal cords by the inhalation of tobacco smoke with incessant frequency. Cancer of the skin, though usually slow in becoming generalized, always originates either in some chronic crack, or from chronic irritation in the substance of some long persistent wart or mole.

The general principles which should govern the prophylaxis of all such growths is that care should be taken to promote healing of any crack or ulceration about any of the orifices of the body, and that any persistent wart or mole which is observed to increase in size, or change in appearance, after its possessor is reaching middle age, should be promptly removed either by the knife, a freezing mixture, or by the use of radium or the x-ray (which are here probably curative) before they undergo any definite malignant change.

The general principle that there is no sharp line between the benign and the malignant, but that the malignant usually arises from the benign is here, as everywhere, perhaps the most important item in the newer knowledge of malignant disease.

The cases used were selected in most instances not only in illustration of the most important of the principles involved, but also as evidence of the present position of many of the profession in relation to them. It seems clear, not only from personal experience, but also from the studies of others as reported in recent literature that all the more modern views of the natural history and principles of management of malignant disease are not as yet the "common knowledge of the profession." It seems clear also that it is important both to the public and to the profession itself that they should become "common knowledge" as rapidly as possible.

Original Articles.

THE SURGICAL TREATMENT OF CANCER OF THE CERVIX UTERI.

By FARRAR COBB, M.D., BOSTON,

Visiting Surgeon to Massachusetts General Hospital.

IN 1912¹ and again in 1914² articles by me on Cancer of the Uterus were published in this JOURNAL and I welcome the opportunity to review my previous conclusions and to incorporate in the present paper the results of an added year of work.

I am able to analyze a series of cases from 1900 to 1914 inclusive, fifteen years, at the Massachusetts General Hospital, 420 in number, 98 of which were personal cases of my own. During the past year I have improved upon my original technic in the operation of hysterectomy, and, also, have devised and performed a new operation for the removal of the uterus, vagina and rectum in those cases in which the disease has invaded the posterior vaginal wall and recto-vaginal septum, cases hitherto considered inoperable. I have continued to add to the series of cases in which I have tied the internal iliac arteries as a palliative measure in the advanced cases, and, during the last six months, have had some experience with the elaborate and valuable method of Dr. James F. Percy³ of Galesburg, Ill., in the use of the actual cautery.

I wish again to emphasize the importance of early diagnosis of cancer of the cervix and to prove that the radical abdominal operation does cure a large percentage of cases and carries with it in skilled hands no excessive primary mortality.

In discussing the radical operation and the late results, the cases of cancer of the cervix have been separated from those of cancer of the body of the uterus because cancer of the fundus is a comparatively favorable form for cure by a simple hysterectomy. The important part of our work from an educational point of view is concerned with this form of uterine cancer. Wertheim's⁴ reported cases are cancer of the cervix.

By radical operation is meant substantially the Wertheim abdominal hysterectomy with certain modifications of my own. This consists of the removal of the uterus and a liberal portion of the vagina and as much of the parametrium as possible through a median abdominal incision after ligation of both internal iliac arteries; the regional lymphatic glands being removed only if enlarged to sight and palpation. This is a difficult and tedious operation and the profession and public must be made to understand that it should be done only by specially trained men. When done by such trained men it should carry with it an immediate mortality of not over 15%.

I have been interested in the radical abdominal operation for cancer of the cervix since 1901, and up to June 1, 1915, have done the extended abdominal hysterectomy 42 times, 31 cases at the Massachusetts General Hospital and 11 in my private work. My immediate mortality at the Massachusetts General Hospital has been 16.1%, in my private clinic 9%, an average immediate mortality of 12.5%.

In this time, out of the total 420 cases of cancer of the uterus, both cervix and body, at the hospital there were performed by the different surgeons 152 hysterectomies of all kinds. The difficulties of securing final information in such a large number of cases has been great, especially in the hospital cases. I feel considerable satisfaction, however, in that out of 116 cases surviving hysterectomy all but 10 have been traced. I have not lost track of any of my own cases, and can report a gratifying percentage of cured cases which will be given later in detail.

There is an appalling lack of operability in the cases presenting themselves, especially at the hospital clinics. While education of the public and the medical profession in regard to the importance of early diagnosis may increase the percentage of operable cases, the insidious onset of this terrible disease will always militate against a certain percentage of the cases coming to the surgeon in time to be cured by radical operation. There is urgent need for education on cancer of the cervix. Over three-fifths of the patients presenting themselves at hospitals, and this is true of the Massachusetts General Hospital, come too late for any attempt at a radical cure, and over three-fourths of those operated on by surgeons not especially experienced in the radical operation die inside of five years. This is due to popular ignorance as to the nature of the disease and its insidious onset, to the neglect of medical practitioners to examine their cases or to recognize the importance of conditions found upon examination, and also to the lack of knowledge on the part of many surgeons as to what is an operable case.

Our efforts to educate the community should be unsparing. A publicity campaign has been carried out to a certain extent by the committee of the American Medical Association in the last two years, but in the last year at the Massachusetts General Hospital it is a fact that the percentage of operable cases was less than any year before in spite of our selective system and attempts to educate the community.

Of the Massachusetts General cases, 4 refused operation, 63 were totally inoperable, 201 could have only a palliative operation; 152 had some form of hysterectomy. In other words, 264 cases came too late for cure, an operability of 36.1%. According to Wertheim's latest statistics 50% of his cases were operable.

Palliative Treatment of Advanced Cases. It is a duty in every case where a radical operation cannot be done to make repeated efforts for pro-

longing life and the checking of pain and hemorrhage. Much too often these advanced cases are neglected and allowed to die without much being attempted for their relief.

The use of the actual cautery with ligation of the internal iliac and ovarian arteries will prolong life for many months and stop pain and hemorrhage. The method of using the cautery should be that devised by Dr. Percy. Previous to becoming familiar with Dr. Percy's work I had been ligating the internal iliac arteries and then using the old-fashioned method of curetting away the disease and charring with a cherry-red cautery iron.

In my experience, ligation of the iliac and ovarian arteries alone is a valuable means of stopping pain and hemorrhage. This method, which I first thought original with myself, was previously done, however, by Charles Ryall,⁵ surgeon to the Bollingbrooke Hospital and Cancer Hospital of Brompton, England. He has reported over twenty cases of ligation with decided benefit and no complications.

Including the cases done by the Percy technic in the last four months, I have tied the internal iliac arteries in 23 cases, with no immediate mortality. In one case, in which enlarged iliac glands were adherent to the vessels, I tore the internal iliac vein, but was able fortunately to apply ligatures above and below the tear. Slight pain and swelling in the extremity followed, but disappeared in two weeks.

My method is, through a median incision, to ligate the ovarian arteries, then open the broad ligaments and identify the ureters and vessels and gently separate the internal iliac arteries from the underlying veins, pass the ligature carrier away from the veins and ligate the arteries with silk. Theoretically, by this method the blood supply to the uterus is reduced and the malignant growth starved.

In my last paper on this subject I gave an abstract of two cases in which ligation of the internal iliac arteries had been done, to illustrate the relief from pain and hemorrhage.

I have come to believe that curetting should not be done because of the chance of forcing cancer cells into the lymphatics. Everything that can be done with the curette can be done by the cautery. Years ago Byrne⁶ in his valuable work said that the cautery itself probably has a positive influence in checking cancer growths much deeper than the surface actually cauterized. In other words, there is hardly any doubt that the developmental activity of the cancer cells is arrested and destroyed at a distance remote from the surface upon which the cautery is used. This is the theory upon which Percy has based his work. According to Percy a temperature of 113° F will kill cancer cells, while normal tissue cells will stand from 130 to 140° F. In his cautery and special water-cooled specula and his method of using them he has made a very valuable contribution to the treatment of cancer of the cervix, especially in

its later stages. Percy himself believes that his method *may* supersede the radical operative treatment in all cases, but states that it is too soon to prove this by statistics of his cases. Briefly, his method is as follows: He opens the abdomen in the median line and ties both internal iliac arteries and the ovarian arteries. After this, with his assistant's hand in the abdomen, over the uterus, he uses through a special water-cooled vaginal speculum for from thirty to fifty minutes his special cautery at a low temperature, what he calls a "cold iron," the heat of which is not sufficient to char or carbonize the tissue, about 125° F.

From seeing Percy's own work, assisting him at operations, and from using his instruments and technic myself I have come to the following conclusions: that his method is the method of choice in treating border-line and advanced cases of cancer of the cervix; that it is too early to pass accurate comparative judgment upon the value of his method in prolonging life as contrasted with former methods, and especially as to the curative value of his technic as compared with the radical hysterectomy. Time is necessary to decide this, several years yet.

I believe, as before, that in the earlier stages of the disease the extended radical hysterectomy is the method of choice, that in the advanced cases we must use the Percy method because by this we can give the most thorough application of heat with the greatest factor of safety and probably the greatest palliation. In other words, in these advanced cases we no longer have any right to use the old fashioned method of curetting and cauterization, and must offer our patients Percy's technic. Also, I believe that the moderately advanced cases which we have operated on radically in the past, should have the Percy treatment first and later the abdominal hysterectomy.

The cases in which I have used this method have had little pain and discomfort and surprisingly little sloughing and foul discharge following the long application of heat. They have been done too recently to enable me to form any conclusions in regard to the progress of the disease.

I want to emphasize the fact that the Percy operation is to be judged only from a series of cases operated on by men who *understand* the technic. It is not to be done by unskilled men and there is danger in its *indiscriminate* use of depriving certain women of their chance of life by radical operations. It is not a *cure-all* in cancer of the uterus, but has an undoubted value in selected cases.

S. M. Clark,⁷ professor of gynecology in Tulane University, New Orleans, has published a preliminary report of his experience with the Percy method. He has had 25 cases of all kinds. He does not feel that the Percy method will supplant the radical operative treatment except in the borderline and advanced cases, but he has used it as a preliminary step in his radical op-

erations. After he has opened the abdomen he has introduced the cautery well into the uterus and raised the temperature to a point where it can barely be tolerated by the hand over the uterus, maintaining the heat from ten to twenty minutes. He thinks that by so doing he may kill some cancer cells and diminish the chance of implantation metastasis.

I quote his conclusions: "Finally, as yet no true end results can be deduced from my cases, but from the temporary results obtained we feel encouraged and believe that in Percy's elaborate heat method a definite advance has been made in the treatment of cervical carcinoma, and not only is it a most valuable agent in managing advanced carcinoma, but when combined with the extensive removal of the uterus our percentage of cures will be, as we hope to show in a subsequent report, definitely improved."

This method of cauterization can and often should be repeated several times in individual cases. Percy states that he has opened the abdomen and used the cautery according to his technic, four or five times in certain cases. The need or usefulness of so many abdominal incisions is to my mind debatable. Clark also feels in doubt about this.

Between cauterizations it is to be remembered that some good can be accomplished by local applications to the cervix and vagina,—acetone, formalin or iodine. The value of radium is uncertain, but in cases in which this treatment can be obtained it should be tried. My own preference is for vaginal douches of formalin 1 to 1000 and the application of formalin 1 to 200 locally through a speculum.

What Cases Should be Operated Upon Radically? If the entire pelvis is filled with a hard mass, the uterus firmly fixed and the vagina markedly involved, no one can have any doubt but that such a case is inoperable, but there are numerous cases in which no bimanual examination, with or without anesthesia, can determine positively that the case is not one for radical treatment, because fixation of the uterus and indurated masses in the pelvis are not infrequently due to inflammatory tissue, adhesions, pus tubes or cysts. In such cases an exploratory laparotomy is necessary to settle the question of radical operation, and since the Percy treatment to be successful demands opening the abdomen, if the case is determined inoperable, the conditions are favorable for applying his treatment with heat. After opening the abdomen, before deciding the question of operability, a thorough survey of the glandular conditions is necessary, and it should be understood that to do this properly the peritoneum must be split and the great vessels laid bare, for in no other way can it be determined accurately whether the glands are pathological. If numerous and large nodes are felt, especially in the sacral chain, the radical operation is inadvisable and the Percy operation should be chosen. Moderate involvement of the iliac and obturator groups does not

contra-indicate an extended hysterectomy. Cases in which the sacral and inguinal glands are involved are absolutely unfavorable. Enlarged iliac glands are not necessarily cancerous by any means.

Even if fixation and induration in the broad ligaments is due to cancer, such cases should have the advantage of exploratory laparotomy, because it is certain some of the apparently desperate cases, even those involving the bladder, can be cured. Of Wertheim's cured cases there were no less than ten that had been considered inoperable by very worthy men. In nine others the wall of the rectum was involved, and in six others the bladder was so fixed that its loosening was very difficult. In several others the parametrium was so widely infiltrated that in separating it from the pelvic wall it gave the operator the impression that he was cutting through cancerous tissue. One of my own cases that has lived longest free from recurrence,—namely, fourteen years, was a case in which the left ureter had to be dug out of a mass of apparent disease in which the iliac glands on both sides were markedly enlarged and were removed but were not cancerous. This is the case of Elizabeth C., W.S., vol. 369, page 120. In her case there was marked thickening and induration in the left broad ligament noted before operation. One other case of mine in which the uterus was fixed and both broad ligaments indurated, is alive and well over six years after hysterectomy. Case of Rose S., E.S., vol. 620, page 105. I have operated on three cases previously operated on palliatively by other men. In each case I have found it possible to do a radical operation; in two of them the bladder was opened and successfully repaired. One died of recurrence, one year, eight months and nine days afterwards; the other two are *cured*. The border-line cases, however, which are most difficult of operation and in which the chances of immediate mortality are great and the probability of rapid recurrence almost certain, should be treated by the Percy method.

The general condition of the patient must be considered carefully in deciding upon the operation, and the long, tedious and frequently bloody abdominal operation should never be attempted in feeble subjects. It is contra-indicated, also, in the presence of marked adiposity. In such cases vaginal hysterectomy or the Percy operation should be substituted. In certain of the adipose cases it may be possible to do a paravaginal or radical vaginal hysterectomy, the operation of Schuchardt⁸ and Schauta.⁹ My own experience has convinced me that the Wertheim operation in very fat women is one of extreme difficulty and risk. One of my fatal cases was that of a very fat woman in whom a vaginal hysterectomy was impossible on account of the inability to pull down the uterus because of firm intra-abdominal adhesions subsequent to a previous laparotomy. Death resulted from general peritonitis.

Thorough Pathological Examinations. The most favorable cases for cure are those in which the diagnosis of cancer is made early by the microscope. Unless great pains are taken, pathological examinations of tissue from suspected areas may fail to discover the disease. Possible sources of error are depending upon curetting without excising pieces, failure to obtain tissue from the diseased region, and especially incomplete study of the disease after removal. Wedge-shaped pieces should be cut from more than one place on the suspicious cervix, should involve the area of granulation tissue and the normal mucosa adjoining, and many serial sections should be cut and examined with care.

As stated in one of my previous papers as an illustration of the possibility of error, there were three cases in our hospital series in which no operation was done because the pathological reports were, in one case, "blood clot"; and in two, "simple glandular hypertrophy." All three of these cases died of typical cancer of the cervix clinically.

Technic of the Extended Abdominal Hysterectomy. The most important factors in the operation are:—

- Anesthesia.
- Abdominal incision.
- Handling of the ureters.
- Control of hemorrhage.
- Removal of the parametrium and glands.
- Prevention of peritoneal infection and implantation metastasis.

In my previous papers I have described some original technic by which I thought the Wertheim operation would be even more radical and perhaps somewhat safer, referring especially to the combined method of spinal and ether anesthesia, abdominal incision, the retraction and elevation of the ureters by tapes and the ligation of the internal iliac arteries. My work during the last year has caused me to modify my technic but little, with the exception of the use of the Percy cautery in the preliminary preparation of the patient (as the first stage of the operation).

Preliminary Preparation. Under this heading is to be considered the general preparation of the patient and also the preliminary preparation of the vagina. Especial attention should be paid to the condition of the heart and kidneys, and the functional renal test should be done with care more than once. A percentage of twenty-five prohibits a radical operation.

Since the introduction of the Percy method it should be stated that *all* cases on which a radical hysterectomy is to be considered should have the Percy method to a certain extent used before the hysterectomy. The important thing to decide is what cases should have the cauterization and the hysterectomy done at one sitting, and, on the other hand, what cases should have the thorough Percy treatment for the maximum time limit for weeks before the hysterectomy. It

is possible that time and further experience will change my present views. I believe now that curetting should never be done, but that the diseased areas should be destroyed with the cautery. In early cases where the area of the cervical disease is small, the method of Clark previously described in this paper, of destroying the diseased area and then inserting the Percy cautery well into the uterus and leaving it from ten to twenty minutes before going on with the abdominal technic is the desired method, and that in the more advanced cases in which there is a moderate or a large amount of proliferative disease, that the complete Percy method should be used for a considerable period of time before the hysterectomy. How long one should wait before doing the complete operation after the Percy treatment is problematical and will differ in individual cases, depending upon the amount of sloughing and vaginal discharge. Usually about one month is needed. Theoretically the completed operation should be done just as soon as possible after the Percy treatment, just as soon as the offensive vaginal discharge has cleared up. Such cases should be treated after the cauterization with strong formalin douches, 1-1000 twice a day and the direct application of strong formalin packs.

I believe there are no cases in which my previous method of doing hysterectomy, even in the early cases, without the use of the cautery can be defended. The cautery should be used in every case, remembering the theory of heat and its influence in destroying cancer cells at a distance remote from the surface. The operator must decide in each individual case whether it is better to use the modified Percy treatment for a short length of time immediately preceding the hysterectomy, or the extended Percy method and the delayed hysterectomy. The decision will be influenced by the extent and exuberance of the disease and the amount of hemorrhage, sloughing and foul discharge.

The preparation of the vagina subsequent to cauterization or in any case in which hysterectomy is to be done, should be by tincture of iodine and alcohol. The vagina should be filled with the iodine and this should be allowed to remain for two minutes. After wiping this out with gauze sponges the vagina is filled with alcohol, pains being taken afterward to wash out the alcohol with bichloride solution.

Anesthesia. During the last year I have continued to use in every case the combined spinal and ether anesthesia as described in my last paper. I am more than ever convinced that this method is of great value in preventing shock.

An intra-spinal injection of from 1-2 c.c. of tropacocaine, 5% with suprarenin, is given between the second and third lumbar vertebrae. This injection is used as a "nerve bloc" on the theory advanced by Crile, the idea being to shut off the nerve irritation from the extensive manipulation in the pelvis from the higher centres. Ether is given at once after the spinal in-

jection and continued through the operation. In my last paper I showed charts illustrating the entire absence of shock by this method. The preparation of the vagina and the use of the cautery can be begun immediately after the spinal injection. Half an hour before the anesthesia morphine grains $\frac{1}{4}$ with atropine gr. 1-120 is given hypodermatically.

I have yet to have any experience in the use of spinal anesthesia in the complete Percy method, neither have I attempted a hysterectomy under spinal anesthesia. Wertheim states that he has done the hysterectomy under spinal anesthesia in 33 cases. It may be said that the duration of spinal anesthesia is too short for the proper performance of the hysterectomy. It is my intention to use the spinal anesthesia to a certain extent in the Percy method.

The Incision. The satisfactory completion of this operation with wide removal of the parametrium and upper portion of the vagina necessitates a generous exposure of the pelvic field. The incision should be in the median line and should go down into the symphysis and always must be carried above the umbilicus. I have in most cases adopted a modification of Gibson's method of operating for low ureteral stone, namely, cutting across the anterior sheath of the recti just above the symphysis. This alone gives appreciably more room. In obese cases I do not hesitate partly to divide the tendinous insertions of the recti muscles. It is a relatively easy matter to repair the recti by mattress stitches at the end of the operation.

Management of the Ureters. The most important technical part of the hysterectomy is the dissection and handling of the ureters, freeing them from the parametrial tissues and lifting them up and out of the pelvis, at the same time preserving their blood supply and avoiding subsequent ureteral fistula. It is not necessary to insert ureteral bougies as aids, but on the other hand, it is a distinctly dangerous procedure and leads to necrosis and fistula formation. To quote from my previous paper, "It is seldom difficult to locate the ureters if one begins to look for them high up near the bifurcation of the iliac arteries. In obese patients, and cases which are complicated by old pelvic infection with adhesions, the finding and isolating of the ureters may be most difficult."

I have perfected an original method by using tapes to retract and lift the ureters out of the way, protecting the ureteral blood vessels by rolling over a fold of the peritoneum. After the ovarian artery has been tied and the broad ligament opened up, the peritoneum being divided above the bifurcation of the iliac arteries, the ureter is exposed lying on the inner and posterior flap of the broad ligament. The internal iliac artery is then exposed and ligated with chronic catgut, after which the posterior peritoneal layer of the broad ligament is incised below the ureter midway between the bifurcation of the iliac arteries and the uterus, parallel with

the ureter and about half or three-quarters of an inch away from it, and through this slit, tapes one-half an inch wide, wet with sterile salt solution, are passed, surrounding the ureter. Traction on these tapes serves to roll a cuff of peritoneum about the ureter; this cuff can be more definitely demarked by vertical incisions. I found that with this method I could make fairly strong traction on the ureters without damaging their blood supply.

There were in my previous paper diagrammatic drawings showing the method of applying the tapes. As I have said before, I have found the method to be of great value in dissecting the vesical end of the ureter, and also, more especially, when dividing the parametrium and cutting across the vagina. In my more recent operations I have not hesitated to use additional tapes under the ureter itself close to the bladder in the final stage of the operation, using gentle traction. I have never had a ureteral fistula, although in many cases I have made fairly strong traction on the ureters.

Prevention of Infection and Implantation Metastasis. Next to the dissection of the ureters I consider the most important part of the technique the method to prevent septic or cancerous infection. The source of infection, obviously, being the ulcerated, infiltrated growth of the cervix, and the presence of discharges and organisms from the growth in the vagina in spite of all attempts at sterilization. One of my fatalities was due to a rapid septic peritonitis. Three of my recurrences have been rapid metastases in the pelvis, presumably implantation metastases. There are only two methods to consider from the point of view of avoiding infection. One devised by Werder,¹⁰ of Pittsburg, in this country, is technically too difficult and dangerous to be considered as a routine procedure. In this method the vagina is freed very far down from the bladder and rectum, and then the uterus is pulled and pushed out through the vulva and the vagina amputated from below with the patient in the lithotomy position. This method has been called an invagination from above. Wertheim tried and abandoned it because of its great difficulty and the serious bleeding from the para-vaginal tissues and the extra time required. I, also, have attempted this method, but have given it up for the same reasons. The second method, the use of the right-angled clamps devised by Wertheim, in my opinion, is the method of choice. To amputate the vagina I use the cautery with a strong right-angled blade.

The thorough use of the Percy cautery in the preliminary preparation in the method previously described is much more important, however, than the use of the right-angled clamps.

Ligation of the Internal Iliac Arteries. In the last year I have continued to ligate the internal iliac arteries in the earlier stages of radical hysterectomy in every case and I am sure that this does not interfere with pelvic nutrition and

does not increase the chances of sepsis and necrotic sloughing, nor cause post-operative cystitis. All the cases in which I have ligated the iliac arteries have been remarkably free from complications of sepsis or cystitis in their convalescence, fully as much, if not more so, than in the cases in which the arteries were not tied. It is my opinion that the iliac ligation simplifies the operation, enables a much clearer dissection and easier freeing of the bladder and diminishes arterial bleeding deep down along the vagina and rectum.

Drainage and After-treatment. I have come to rely almost entirely upon vaginal drainage with iodoform gauze. It is possible that in a very few cases, where there has been unusual infection of the peritoneum from complicating pus tubes, or where the bowel has been injured or the bladder resected, abdominal drainage may be advisable. During the last year I have used no abdominal drainage in any case.

The after-treatment is that of any abdominal operation, except that it is well to elevate the head of the bed about eighteen inches for the first week and to use an in-lying catheter for the same length of time together with urotropin. The majority of my cases have had a surprisingly satisfactory recovery and have been singularly free from any complications.

Preliminary Report of a New Method of Operating for Cancer of the Cervix, the Posterior Vaginal Wall and Recto-Vaginal Septum. The following operation has been performed by me with technical success and will be reported in detail in an illustrated article later. I suggest it as an operation for the possible cure of cases of squamous cell carcinoma of the cervix which start from the portio-vaginalis of the cervix, and while involving the cervix to only a moderate extent, have extensively invaded the vaginal wall and the recto-vaginal septum, cases in which the cervix is but slightly involved and the main portion of the disease is confined to the vagina. This operation necessitates the removal of the uterus, parametrium and posterior half of the vaginal tube and a portion of the rectum. It should be done in two stages. This operation is no more radical in its extent than the two-stage operation for cancer of the rectum, and I firmly believe has a distinct value in such selected cases, cases which hitherto have been considered inoperable.

In the first stage the cervical and vaginal disease is thoroughly treated by the Percy method for thirty minutes. Immediately following this the steps of my radical abdominal hysterectomy are followed in every detail with this exception, that after dividing the parametrium with the cautery knife the cervix is cut across supra-vaginally and thoroughly charred intra-abdominally, using the abdominal water-cooled speculum. The cervix is destroyed with the cautery, leaving only a thin shell of tissue between the pelvis and the vagina. The ureters are looped up with catgut and fastened away from

the remains of the cervix and the field of the second operation in such a way that they will not be kinked. The median incision is then closed without drainage and a left inguinal colostomy made.

The second stage can be done in from three to four weeks afterward, depending upon the condition of the patient and the amount of vaginal sloughing and discharge. It can be done under spinal anesthesia if desired. With the patient in the lithotomy position the Schauta lateral incision through the para-vaginal and para-rectal tissues to the hollow of the sacrum is made and the remains of the cervix and posterior half of the vaginal tube and as much of the rectum as necessary removed.

Causes of Death and End Results in My Personal Cases. As stated earlier in this paper, I have done 42 radical (Wertheim) hysterectomies, 31 at the Massachusetts General Hospital and 11 in my private practice. In these 42 hysterectomies I have had 6 deaths as a direct result of the operation, an immediate mortality of 14+%. The causes of death were as follows:—

One case died on the second day of general peritonitis, an extremely difficult case of a very obese woman; one in twelve hours of shock; one on the tenth day, cause of death not made out at autopsy; one the fifth week of iliac thrombophlebitis; one on the tenth day of intestinal obstruction; one in the sixth week of intestinal obstruction, for which enterostomy had been done.

Six of my cases have been done over five years ago; one of these died in thirteen months from recurrence in the pelvis with obstruction of the ureter, the five others are alive and free from recurrence from six to fourteen years. Thirty cases have been done since August, 1911. Five of these developed rapid recurrence in the pelvis within from three to six months after the operation and died a few months afterward. Five cases are alive and well over three years without recurrence. Fourteen are alive and free from recurrence from one to two years. Six have been done in the last six months and are free from recurrence as yet.

ANALYSIS OF ALL CASES OF CANCER OF THE UTERUS, BOTH OF THE CERVIX AND BODY, AT THE MASSACHUSETTS GENERAL HOSPITAL FROM 1900 TO 1914 INCLUSIVE:

Total number of cases.....	420
Personal cases of Dr. Cobb.....	98
Refused operation.....	4
Inoperable.....	63
Palliative operations.....	201
Vaginal hysterectomies.....	19
For cancer of cervix.....	14
For cancer of fundus.....	5
Abdominal hysterectomies.....	133
For cancer of cervix.....	104
For cancer of fundus.....	29
Operability.....	36.1%
264 came too late.	

ANALYSIS OF THE RADICAL (WERTHEIM) HYSTERECTOMIES AT THE MASSACHUSETTS GENERAL HOSPITAL FROM 1900 TO 1914 INCLUSIVE:

Total number of cases.....	55
Immediate mortality.....	12 or 21.8%
Surviving cases.....	43
Traced.....	43
Operated on over 5 years ago.....	14
Alive and free from recurrence over 5 years.....	7 or 50 %
Alive and free from recurrence over 3 years.....	12

ANALYSIS OF PERSONAL CASES OF DR. COBB AT THE MASSACHUSETTS GENERAL HOSPITAL FROM 1900 TO 1914 INCLUSIVE:

Total number of cases.....	31
Immediate mortality.....	5 or 16.1%
Cases traced.....	All
Operated on over 5 years ago.....	6
Alive and free from recurrence over 5 years.....	5 or 83 %
Alive and free from recurrence over 3 years.....	10

SUMMARY OF MY RADICAL HYSTERECTOMIES AT THE MASSACHUSETTS GENERAL HOSPITAL DONE OVER A YEAR PREVIOUS TO JUNE 1, 1915.

Elizabeth C., W.S., vol. 369, p. 120, Jan. 4, 1901, age 35 years. Symptoms: pain and flowing for six months. Had been curetted by a doctor. Cervical growth size of half a dollar, marked thickening and induration in left broad ligament. Iliac glands on both sides removed.

Pathological Report. Squamous cell carcinoma of the cervix; glands not malignant.

Alive and free from recurrence, June 1, 1915, fourteen years and five months.

Deborah M., Hospital No. 128406, August 6, 1902, age 37 years. Symptoms: continuous flowing without pain for two months. Moderately extensive cancer of the cervix. Uterus movable, broad ligaments not thickened. One enlarged iliac gland on the left removed.

Pathological Report. Squamous cell carcinoma of the cervix.

Death in thirteen months; recurrence in the pelvis.

Madeline V., Hospital No. 134507, S.S., vol. 83, p. 287, Oct. 16, 1903, age 48 years. Symptoms: for five months excessive flowing and pain. Extensive cauliflower growth of cervix, uterus movable. No thickening in the broad ligaments. No glands removed.

Pathological Report. Squamous cell cancer of the cervix.

Alive and free from recurrence June 1, 1915, eleven years and eight months.

Jane S., Hospital No. 140882, S.S., vol. 107, p. 143, Jan. 14, 1905, age 60 years. Symptoms: for two or three years bloody discharge, some pain, loss of weight and strength. Cervix hard and indurated, several deep ulcerations, uterus movable, broad ligaments not thickened. One enlarged gland in the left iliac region removed.

Pathological Report. Squamous cell cancer of the cervix; gland non-malignant.

Alive and free from recurrence June 1, 1915, ten years and four months.

Ethel H., Hospital No. 150169, S.S., vol. 137, p. 23, Nov. 6, 1906. Age, 27 years. Symptoms: for five months flowing and pain. Had been curetted by a doctor. Badly eroded cervix with free hemorrhage. On examination broad ligaments not indurated. Bladder torn in operation. Iliac glands on left enlarged and removed.

Pathological Report. Squamous cell cancer of the cervix; glands non-malignant.

Alive and free from recurrence June 1, 1915, eight years and seven months.

Rose S., Hospital No. 159940, Aug. 24, 1908, age 25 years. Symptoms: for fourteen months constant flowing and foul discharge. Cervix hard, nodular and excavated. Uterus not freely movable. Induration in both broad ligaments. No glands removed.

Pathological Report. Squamous cell cancer of the cervix.

Alive and free from recurrence June 1, 1915, six years and seven months.

Isabelle B., Hospital No. 177394, July 25, 1911, age 35 years. Border-line case that had had previous amputation of the cervix. Broad ligaments extensively involved in the disease. Left iliac glands markedly enlarged and cancerous. Bladder opened.

Pathological Report. Squamous cell cancer of the cervix. Lymph glands metastatic. Carcinoma.

Case recovered from operation but had rapid recurrence within two months but lived two years after operation. Died July 31, 1913.

Matilda R., Hospital No. 178765, Oct. 10, 1911, age 50 years. Symptoms: for four months irregular hemorrhage, vaginal discharge and pain in back. Attempted vaginal hysterectomy because of adhesions unsuccessful. Subsequent abdominal hysterectomy.

Pathological Report. Squamous cell cancer of the cervix. Death in forty-eight hours of septic peritonitis.

Anna M. M., Hospital No. 185720, Jan. 1, 1912, age 39 years. Symptoms: for four weeks pain in left iliac region with uterine hemorrhage. Induration in the right broad ligament. Preliminary curetting and cauterization and nine days afterward abdominal hysterectomy. No glands removed.

Pathological Report. Squamous cell carcinoma of the cervix.

Case alive and free from recurrence June 1, 1915, three years and five months.

Clara A. J., Hospital No. 180385, Jan. 9, 1912, age 39 years. Symptoms for two months. No preliminary cauterization. Radical abdominal hysterectomy. Bladder opened and sutured. No glands removed.

Pathological Report. Squamous cell carcinoma of cervix.

Died in fifth week of septic iliac thrombosis.

Fannie S., Hospital No. 180965, Feb. 10, 1912, age 33 years. Symptoms: for one month previous, flowing and foul discharge. Occasionally pain in right side. Diagnostic curettage and removal of specimens.

Pathological Report. Simple glandular hypertrophy.

Nov. 13, 1912, re-entered the hospital. Radical

hysterectomy. One iliac gland on right size of bean removed.

Pathological Report. Early squamous cell cancer of cervix. Gland not metastatic.

Alive and free from recurrence June 1, 1915, two years and six months.

Laura E. T., Hospital No. 182059, April 10, 1912, age 48 years. Symptoms: excessive flowing for two months. Extensive cauliflower growth of cervix. Broad ligaments not indurated. Radical abdominal hysterectomy. Enlarged and hard glands from the bifurcation of both iliaes removed.

Pathological Report. Squamous cell cancer of the cervix. Lymph nodes not metastatic.

Recurrence in pelvis within six months. Died Sept. 10, 1914.

Mary J. M., Hospital No. 184450, Aug. 17, 1912, age 42 years. Symptoms: for two years hemorrhage, foul, watery discharge, no pain. Inverted type of cancer of the cervix. Uterus freely movable. Radical abdominal hysterectomy.

Pathological Report. Squamous cell cancer of the cervix.

Death from shock in twelve hours.

Annie O., Hospital No. 185280, Oct. 2, 1912, age 38 years. Symptoms: for three months profuse flowing, pain in back, uterus fairly movable, cervix ulcerated and eroded. One-stage operation, curette and cautery followed by abdominal hysterectomy. Large glands from both iliac regions removed.

Pathological Report. Squamous cell cancer of the cervix. Metastasis in iliac glands.

Recurrence in pelvis within two months. Vaginal growth curetted and cauterized Dec. 16, 1912. Death, March, 1913.

Philomena B., Hospital No. 186643, Dec. 19, 1912, age 43 years. Symptoms: for five months irregular flowing, no pain. Uterus movable. No induration in broad ligaments. Cauterization preliminary to hysterectomy. No glands removed.

Pathological Report. Adeno-carcinoma of cervix. Death in ten days. Cause of death not determined at autopsy.

Alice M. M., Hospital No. 178486, Feb. 6, 1913, age 50 years. Symptoms: for two years vaginal discharge and bleeding. Large cauliflower growth on cervix. Uterus moderately movable. Two-stage operation, amputation of cervix and cauterization three weeks previous to radical hysterectomy. No glands removed.

Pathological Report. Squamous cell cancer of the cervix.

Alive and free from recurrence June 1, 1915, two years and four months.

Bernesse S., Hospital No. 189215, May 19, 1913, age 33 years. Symptoms: for two months irregular flowing. Uterus movable, cervix—cauliflower growth. Preliminary cauterization, radical hysterectomy three weeks afterward. No glands removed.

Pathological Report. Squamous cell carcinoma of cervix.

Recurrence in the stump of the vagina in six months. In eight months recto-vaginal fistula. Death, July, 1914.

Mina C. McW., Hospital No. 189708, June 18, 1913, age 40 years. Symptoms: for over a year abdominal pain and excessive flowing. Loss of forty pounds in weight. Cervix extensively involved, uterus fairly movable. Preliminary cauterization. Radical operation within three weeks. No glands removed.

Pathological Report. Squamous cell carcinoma of the cervix.

Alive and free from recurrence June 1, 1915, two years.

Zenia S. C., Hospital No. 190040, July 8, 1913, age 65 years. Symptoms: for three months backache and irregular bleeding. Inverting type of cancer. Radical operation. No glands removed.

Pathological Report. Carcinoma of cervix.

Death from probable recurrence in the liver within six months.

Rose A., Hospital No. 190533, Aug. 5, 1913, age 48 years. Symptoms: for six months irregular hemorrhage and discharge. Cervix extensively eroded. Induration in both broad ligaments, uterus not freely movable. Question of involvement of bladder. One-stage operation without cauterization. No glands removed.

No laboratory report, but case absolutely typical one of cancer of cervix.

Alive and free from recurrence June 1, 1915, one year and ten months.

Maud L., Hospital No. 190909, August 27, 1913, age 31 years. Cancer of cervix complicated by pregnancy. Radical abdominal operation; no glands removed.

Pathological Report. Carcinoma of cervix.

Alive and free from recurrence June 1, 1915, one year and seven months.

Wilhelmina G., Hospital No. 191529, Oct. 1, 1913, age 44 years. Symptoms: for five months foul smelling, watery discharge with occasional hemorrhage. Cervix hard and indurated. Uterus somewhat fixed. One stage operation without cauterization. No glands removed.

Pathological Report. Squamous cell carcinoma of cervix.

Alive and free from recurrence June 1, 1915, one year and eight months.

Florence A. D., Hospital No. 192734, Dec. 9, 1913, age 55 years. Symptoms: for four weeks hemorrhage. Hard nodular mass in the cervix extending on posterior vaginal wall, induration in left broad ligament. Radical operation preceded by cauterization. No glands removed.

Pathological Report. Squamous cell cancer.

Lived for two months and died of intestinal obstruction, which necessitated enterostomy.

opened more than once for the reapplication of the heat. In each of two of my cases the abdomen has been opened five times. In one of these the fifth operation was done "on suspicion" that a recurrence was developing in the pelvis. It could not be determined by examination through either the vagina or rectum. A malignant mass was found springing from the pelvic fascia high up on the left side over the ureter and iliac vessels. The heat treatment was applied as thoroughly as the location of the disease permitted, and the abdomen closed. This patient is doing amazingly well, seven months after the date of the fifth opening of her abdomen. She is still under treatment with the deep penetration method of the x-ray from the Coolidge tube. The other case mentioned above is also doing well, and is being treated in the same way by the Coolidge tube.

I mention these two cases, first, to call attention to the fact that the heat can be applied to a malignant mass in close proximity to blood vessels, because there is little danger of damaging important vessels as long as the heating iron is not brought directly into contact with them. The explanation is that the circulating blood maintains the temperature of the vessel wall in much the same way that my water-cooled speculum protects the vaginal walls. The second important consideration, where the abdomen is likely to be opened more than once, is that of abdominal adhesions. If, at the second or subsequent abdominal sections, extensive adhesions are encountered, the operative results outside of the cancer technic are in a fair way to be bad.

I have succeeded in practically eliminating abdominal adhesions by the following technic: first, a ten-yard sponge of baby flannel, six inches wide, wrung out in a 2% solution of sodium citrate in normal saline, is used.³ The abdominal walls are elevated as much as possible during deep anesthesia, and the intestines and omentum are pushed up out of the pelvis and under the upper abdominal walls *without brushing or traumatizing either the visceral or parietal peritoneum*. The edges of the abdominal incision are protected by towels from contact with the sodium citrate sponge for the theoretical reason that it may interfere with good union. All blood is kept out of the abdominal cavity for fear that its organization may result in adhesions. The baby flannel sponge is less likely to traumatize the endothelium than the usual gauze pack. In addition, it more completely excludes the air from the abdominal cavity.

After a rather large experience with cases in which the abdomen has been reopened more than once, I am convinced that these five factors—the sodium citrate, the flannel sponge, lessened traumatism, exclusion of air and exclusion of blood—are of supreme importance in preventing intestinal adhesions.

I also attribute to this technic for preventing abdominal adhesions, an important place in the explanation of the freedom from shock, gas

pains and general suffering, which usually marks the convalescence of my cases of operated uterine carcinoma. This holds even in those cases in which the abdomen has been open two or more hours, as is sometimes true where there is extensive involvement of the pelvic structures.

TECHNIC.

The patient is placed on the table in such a manner that the buttocks *will remain* over the lower edge of the table. This position can be maintained only when the trunk is supported by shoulder braces. The head is dropped so that the vaginal field is brought within easy access of the operator who is to apply the heat through the water-cooled vaginal speculum. The legs are elevated and separated as in any vaginal operation. In elevating the legs, they should not be thrown so far back on the abdomen as to interfere with the freedom of the operator working above. The abdomen is first opened, and the extent of the pelvic and abdominal metastases (if any) determined. Then the intestines are packed off, as already detailed, and the internal iliac and ovarian arteries tied. I have lost four patients from late hemorrhage coming on about two weeks after the application of the heat, where the iliaes were not tied. Since tying the vessels, I have lost no patients from hemorrhage or any other cause, following the operation. In two recent cases the remains of the uterus came away as a great slough, leaving a healthy granulating surface.

While the vessels are being tied, the assistant can dilate the vagina with the vaginal dilator. This dilatation should be persisted in until the vulvar orifice can easily accommodate the water-cooled vaginal speculum. In my own clinic, I have found it useful to have at least three of these specula. The woman who has never borne children, and the woman with a very deep relaxed vagina, of necessity require two different patterns of instruments; even though the vaginal dilator solves the problem in many cases, making the vagina fit the speculum rather than having many specula to fit the vagina.

The instruments devised to most effectively apply this treatment consist, first, of a set of four electric heating irons, which are made either for the 110 or 220 volt current. These heating irons come very near to fulfilling the requirements for perfect instruments in furnishing heat for the purposes of this special technic. They also make ideal general purpose cauteries for heavy or light work. They are practically never out of order, and require no special care. In addition to the heating outfit, the average case for treatment requires a vaginal dilator, a water-cooled speculum, a vulsellum forceps and a wire retractor. The two latter instruments are useful in bringing the outer circumference of a large mass of cancer within the reach of the heating iron. When there is extension of the cervical mass into the vaginal

walls, the water-cooled speculum open at the top gives one a most effective means of applying the heat in its destruction.

My own method of dealing with this condition is to put the heating iron on the bottom of the water-cooled speculum, and place a thermometer in the urethra. When a degree of heat sufficient to maintain the temperature in the urethra at 120° F. (49° C.) is obtained, the thermometer is removed and the speculum slowly rotated until the entire vaginal surface has been treated by the heat. This degree of heat, when sufficiently applied, will alter the color of the vaginal mucous membrane to a sickly yellow, from which it will recover without the formation of scar tissue.

In applying this treatment, I wish to emphasize four very important essentials, in order to insure the greatest probability of success. First, open the abdomen; second, introduce the heating iron through the vaginal or cervical mass to the fundus of the uterus, and hold it there until everything abnormal is too hot to hold in the hand encased in a medium weight rubber glove; third, apply the heat until all the fixed carcinomatous tissues are freely movable; fourth, use a low degree of heat. I want to re-emphasize points two and three. It can be readily seen that if the heating iron is aimlessly moved about, no area of tissue will become sufficiently heated to destroy the carcinoma present. It is absolutely essential, therefore, that the heating head be held in one place until that particular area is sufficiently hot. It can then be moved to another area.

One of the surprising things is the difficulty encountered in getting the heat through the cancerous mass in sufficient degree to be effective. It cannot be done quickly either with a high or low degree of temperature, unless the malignant mass is very small. The heat must be applied until all the fixed pelvic structures are as freely movable as they were normally. This means the inflammatory, as well as the tissues invaded by the malignant process. If any of the pelvic structures remain as they were found before the heat was applied, it can readily be seen that the cancer cells which they may contain have not been altered by the treatment. It requires judgment and experience to do what is here insisted upon as necessary; but the failure to do this will prove to be the stumbling block to the successful and effective performance of this method of treatment.

The technic above outlined removes the gross malignant mass at one sitting. It leaves the small points of metastasis that may remain to be treated by one or more of the many recognized methods of treatment: operative, x-ray, radium or serum. But more than all else, it permits, I believe, the acquired but insufficient resistance, which must and does develop during the progress of the cancerous invasion, to assert itself. From my experience, I am convinced that this acquired resistance, although obviously insuffi-

cient while the gross mass is still present, is in many cases capable of clearing up small points of metastasis after the destruction of this mass.

Finally, we should not forget that many of these patients are dying not from cancer, but from the secondary invasion of destructive septic organisms into the malignant mass. We see the same destructive effects from these bacteria in the last stages of tuberculosis and syphilis. Inoperable cancer, plus the secondary invasion of sepsis-producing organisms, make a picture only too well known for its misery and hopelessness. Heat generously applied, together with the final beneficial results of the natural resistance already developed in the blood, in many cases changes this mass of living despair into one where hope and comfort abound.

A CASE OF PYELONEPHRITIS, COMPLICATED BY ADENO-CARCINOMA AND CHYLURIA.*

By ELIZABETH T. GRAY, M.D., BOSTON.

Visiting Surgeon to New England Hospital.

THIS case which I wish to report is unusual for two reasons—first the adeno-carcinomatous involvement, and second the condition of chyluria which was found.

Mrs. E., widow, 74 years old, born in Maine, was admitted to the hospital April 1. Her family history shows that her mother died of diphtheria, and her father of "cancer of the lip." She has had one child and no miscarriages. Menopause at about 40.

She has had more or less trouble with hemorrhoids during her adult life, these becoming ulcerated at several different times. About 14 years ago the trouble with the kidneys began. She was told by a physician at that time that she had a floating left kidney.

Ten years ago had an abscess somewhere in the urinary region with a discharge of blood and pus from the bladder; but apparently entirely recovered from this condition after a few weeks.

Since then has had several attacks of pain in right hypochondriac and lumbar regions, each lasting from 2 to 5 weeks and occurring every 9 or 10 months. These attacks have been more frequent during the last two years.

Three weeks ago had an attack, during which the pain was almost unbearable, the right side being extremely tender to touch; but she never has had nausea or vomiting with her attacks.

* Read before the New England Hospital Medical Society, May, 1915.

Upon examination we found Mrs. E. cachectic in appearance, thin, almost emaciated, and in a most critical condition.

Temperature 103, pulse 100.

The right abdomen showed a circumscribed, fluctuating mass extending from the line of the ribs to the iliac crest and in as far as the border of the right rectus. The lumbar region showed nothing abnormal. This mass was so tender that examination by palpation was very unsatisfactory.

Examination of catheterized specimens of urine showed (she passed about 500 c.c. in each 24 hours):

	April 2	April 3	April 4
Sp. gr.	1011	1023	1035
Color	Pale straw	Deep amber	Reddish brown
Reaction	Acid	Acid	Acid
	Albumen trace	Trace	Trace
	No sugar	No sugar	No sugar

Sediment: Much fat, so that a stain was left on sides of the glass; a few hyaline casts, and many pus cells. Blood count showed leucocytosis of 24,000.

X-ray Report: "The examination of the right abdomen from crest of ilium to lower ribs shows no outline of kidney. There is present a dense shadow that is very much mottled, but leaves no definite outline." A diagnosis was not made, but further information was asked, especially about the chyluria.

As the patient was in such a critical condition, I did not think it advisable to have the ureters catheterized. From the clinical findings I made a diagnosis of either a pyonephrosis or a pyelonephritis.

On April 5 the patient was prepared in the usual way for abdominal operation.

As the mass was so large, I decided to use the Israel incision, *i.e.* the incision beginning at the middle of the last rib, curving forward and downward and then outward, parallel to the crest of the ilium.

Immediately a large quantity of very foul-smelling pus escaped through the incision. I could not find a kidney upon digital examination, but brought out large quantities of bloody debris, and among this debris several stones, the largest of which measured $1\frac{1}{2}$ cm. by 1 cm.

The cavity was emptied by the hand, and then thoroughly irrigated with normal saline, the extremities of the incision united with through-and-through silkworm gut sutures and a double cigarette drain introduced.

The patient made an uneventful recovery, the temperature on day after operation being 102.5 at 4 a.m. and at 1 p.m. 99.4. The following day the temperature was normal and remained so during convalescence.

The drainage tubes were removed permanently on the tenth day. The patient was discharged May 11 in good general condition and with the incision practically closed.

The amount of urine passed for the first four or five days after operation was very small, average about 200 c.c. in the twenty-four hours, but with diuretics and plenty of water the amount increased until she passed about 1200 c.c. The urine showed neither pus, blood nor fat after the operation.

Pathological Report from Tufts College Laboratory. (Unfortunately this is not complete as the calculi were lost and so could not be examined).

The report reads: Specimen shows debris of right kidney in firmly walled-off pockets, and consists of masses of soft reddish grey friable tissue with abundant clot. Diagnosis, adeno-carcinoma. Swabs from pus show streptococci and staphylococci.

This case was probably a pyelonephritis rather than a pyonephrosis of the right kidney. A pyelonephritis presupposing a suppurating inflammatory process beginning in the renal parenchyma, which may or may not involve the pelvis; the process being either continuous or consecutive; while a pyonephrosis means simply a dilatation of the pelvis and calices with pus. These processes are always of bacterial origin and may be a hematogenous and descending, or urogenous and ascending.

The hematogenous form may follow any of the acute infectious diseases or simple local affections like furunculosis or tonsillitis. Usually this form begins in the cortex, from which the process extends. When the surface of the pelvis has been eroded by a stone the infection continues downward and produces pyelitis.

The colon bacillus is the organism most frequently found, but mixed infection, showing a variety of micro-organisms, is common.

Stone in the kidney or ureter is caused from the inability of the urine to retain in solution certain of its constituents, *i.e.* the urates of Na. and NH₄, uric acid,

oxylate } lime
carbonate } cystin and xanthin

Secondary calculi usually consist of phosphate of lime and develop only in a kidney already the seat of infection.

Often a stone may be carried either in the cortex or pelvis for many years, leading to absolute destruction of the kidney without giving a sign of its presence, renal colic being a very inconstant symptom in a large number of cases.

When infection takes place, a persistent pyuria is present.

Diagnosis of stone can be made fairly easily by the x-ray, but to obtain a satisfactory plate is still one of the difficult feats of radiography. If the x-ray plate is good, it should show the last two ribs, the transverse processes of the lumbar vertebrae and the shadow of the psoas muscle plainly. Then the shadow of even a normal kidney should be seen distinctly and is useful in determining the presence of the second kidney. In enlargement from tumors or distention a positive shadow should always be obtained.

The presence of a stone is revealed by a distinct sharp shadow upon the kidney shadow, but this should be interpreted as a stone only where it is associated with other clinical evidence, because calcified lymph nodes, the thickened tip of an appendix and buried sutures infiltrated with lime salts, after a previous laparotomy, have been mistaken for kidney or ureteral stones.

Tumors of the kidney are rare, only 2% of all

tumors being found in this location, the most common malignant form being the sarcoma. True adeno-carcinoma of the kidney is practically unknown, but quite frequently in conjunction with carcinoma, adenomatous masses are found, and to this condition the term adeno-carcinoma is given.

Again, malignant disease of the kidney is oftenest found in childhood; from 30 to 52% being quoted as the proportion found during the first ten years of life.

Adult life is practically exempt, and the liability increases again in old age.

Tumors of the kidney occur oftenest in men, but are more often inoperable in women, as the earlier symptoms of renal new growth do not attract so much attention in women as in men.

Dermoid cyst, fibroma, carcinoma and adeno-carcinoma are the rarest forms of tumors in the order given above. Adeno-carcinoma usually begins in the cortex, and may destroy the entire kidney without producing any increase in size or alteration of form. Metastases occur, via the blood vessels, in the liver, lungs, retro-peritoneal glands, second kidney, intestines and pancreas.

The prognosis is uniformly bad, most cases being ultimately fatal.

Symptoms: Hematuria, pain and usually tumor. Hematuria is the most common initial symptom, occurring in 70% of the cases. Acute pain in one or both kidney regions is sometimes the earliest symptom. Cachexia usually does not appear until an advanced stage of the disease. Fever does not often occur. The urine may have the color of pure blood or may vary from this to pale straw color; it is clear in about 70% of the cases.

Israel describes worm-like bodies in the urine, which he believes are pathognomonic of malignant tumor. They usually occur in a faintly bloody or clear urine, and consist of a fibrinous ground substance, in which blood cells, leucocytes, fat droplets and swollen epithelium are embedded.

Tumors of the kidney are comparatively slow in growth, often taking from 10-15 years.

Chyluria is a peculiar condition of the urine, in which it presents a more or less milky appearance and contains fat, with more or less albumen. The urine is usually acid, and the sp. gr. varies from day to day. It closely resembles the urine of pyuria, but can be distinguished from it by the microscope, which shows much fat in a fine state of emulsion, leucocytes and red blood corpuscles.

Chyluria is often associated with elephantiasis and lymphangiectasis. Chylous urine may be of parasitic or non-parasitic origin.

The parasitic or obstructive is due to the obstruction of the kidney lymphatics by the *filaria sanguinis hominis* and then their rupture, and the discharge of chyle into the kidney.

The cause of the non-parasitic form is obscure; possibly it is a symptom of malignant tumor of the kidney.

LIMITATIONS OF THE RADICAL OPERATION FOR CERVICAL CANCER OF THE UTERUS.

By HENRY T. HUTCHINS, M.D., BOSTON.

THE doctrine of the early diagnosis of cancer of the cervix has now become sufficiently widespread in almost every community in the civilized world. No medical student graduates from a decent school nowadays who has not had the importance of examination for early cancer thoroughly impressed upon him. Physicians in small communities have heard of it and thoroughly understand it. That many physicians are negligent and lazy in this regard is true and most unfortunate, and for this reason the doctrine should be continually brought before the medical profession.

A sufficient number of surgeons in every city of considerable size have perfected themselves in the performance of a radical operation for this disease so that no woman need lack for proper surgical treatment.

The question of the operability of a certain case, when once it is seen by a competent surgeon is, however, still open for discussion. On this point there is a difference of opinion. One surgeon will operate on every case of cancer of the cervix regardless of its extension, evidently going on the principle that one cannot make a bad condition much worse. Another surgeon will operate only when a radical removal is clearly possible. How then should operability be clearly defined and what should be done for inoperable and border-line cases?

No cases are more distressing than those of cancer of the cervix upon which a radical operation has been performed and the cancer not completely removed and possibly a vesical, rectal or ureteral fistula left. Invariably when this takes place, the patient herself and her relatives are unanimous in declaring that they would much rather that nothing had been done or that death under the anesthetic had relieved the sufferer.

We all realize that it is not possible by digital examination to determine the operability of every case,—that the exploratory incision is frequently necessary; but having made this incision, a conscientious surgeon should then know whether a clean operation can be performed or not. It is at this point that true surgical judgment should be employed and it is here that more surgeons should be willing to stop and back out. It is much easier, once the abdomen is opened, to plunge ahead, almost invariably get into serious trouble, and leave the patient with distressing sequelae, than to close the abdomen and start immediately palliative treatment. We must look at these inoperable or borderline cases, as we should at every case, entirely from the patient's standpoint. If we cannot be sure of having the patient better off with at least a fair chance of a cure, then the complete operation should not be done. A woman

relieved of bleeding and pain, but completely disabled by a urinary fistula and in whom the cancer has not been entirely removed is indeed a pitiable sight.

What I wish to urge then is conservative radicalism in these borderline cases. If doubt exists as to whether a case is operable or not, always open the abdomen and find out, thus giving every case the full benefit of the doubt. The operability can be determined immediately the abdomen is opened. If the base of the bladder is involved, if the rectum is involved, if the carcinoma extends laterally to the wall of the pelvis and surrounds the ureter, and if the iliac glands are involved, only a minimum of these cases will be cured by radical operation and a large number will be left in a hopeless condition. In such cases it is my opinion that we shall better serve our patients by not attempting the radical operation. A resection of the bladder, a transplantation of the ureters, or a resection of the rectum *without* the complete removal of every vestige of cancer, are unjustifiable procedures.

What then shall we do to relieve these cases, leave our patient in better condition and prolong life with the maximum degree of comfort? We have at hand many procedures by which this can be accomplished without injury and incapacitating sequelae. Providing after the abdomen is opened the case is found too far advanced for a clean radical operation, both internal iliaes should be tied and the abdomen closed. This will help to relieve the bleeding and in some measure delay the spread of the growth. The cervix should then be attacked with the slow cautery, taking great care not to char the tissue by too high a degree of heat and apply a low degree of heat for one half to one hour. The heat may be applied at intervals of from two to three weeks. By this means we completely relieve the bleeding and foul discharge by a surgical procedure which involves the minimum of shock to the patient, accomplishes everything that can be done and avoids the unnecessary and distressing fistulae which, even in the hands of the most competent, are altogether too frequent.

It is far from my purpose to decry the employment of the radical operation whenever that operation can be clearly defended, but I feel that in many cases the operation is being performed when the chance of a cure is not even probable, and that by doing so we cannot persuade ourselves that we are giving our patients the greatest chance and are far from giving them the *only* chance. The prolongation of life in comfort is in the great majority of cases to be obtained by the less radical procedure. The advent of Dr. Percy's principle of the long continued application of a low degree of heat will be a great boon to this class of patients.

The campaign for the early examination and diagnosis of cancer must be continued with vigor and the radical operation performed on

all such cases, but in the cases where the early diagnosis has not been made, and those form a large group at present, let us adopt measures which give the maximum of relief and comfort for the remainder of life and the minimum of mutilation, rather than carry the radical procedures to such unfortunate, unfruitful and unsurgical extremes. If we cannot do good let us not do harm and thus bring discredit on radical surgery and attempt to ease our consciences by the plain falsehood that "we have given the patient her only chance."

Book Reviews.

Alone in the Sleeping Sickness Country. By FELIX OSWALD, D.Sc., F.G.S., F.R.G.S. London: Kegan Paul, Trench, Trübner & Co., Ltd. 1915.

In this delightful volume the author depicts the habits and characteristics of the Kavirondo negroes among whom he lived alone at close quarters on the cliffs of the Victoria Nyanza in the heart of Africa close to the equator. Though only three-weeks' journey distant from London, he was there in a primitive civilization essentially identical with that of the early Caledonians of Scotland of whom Herodian writes "They know not the use of clothing but encircle their necks and loins with iron, deeming this an ornament and an evidence of opulence."

The primary object of the author's journey was not medical nor ethnological, but to pursue a geological investigation on behalf of the British Museum of some miocene deposits on the east coast of the lake. This research, however, carried him through the heart of the sleeping sickness country and in two chapters devoted to this subject he describes and discusses the disease, its relation to the conditions of the inhabitants and the means of its treatment and prevention from the valuable point of view of a non-medical scientist. His tastes and interests are refreshingly catholic and he writes with equal fascination and concern of the climate, the geography, the customs of the people, their music, the geology, fossils, scenery and poetic beauties of the land through which he traveled and in which he worked. The book is abundantly illustrated with a colored map and with over seventy plates from the author's photographs. It is a work for the laity as well as for the profession and many a physician might gain by reading it a profitable awakening of his interest, not alone in sleeping sickness, but in the manifold objects and interests which appeal to the scientific and human mind in lands beyond his own.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, JULY 15, 1915

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*
GEORGE G. SMITH, M.D., *Assistant Editor.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

THE PREVENTION AND CONTROL OF CANCER.

At the annual session of the Medical Society of the State of Pennsylvania in Philadelphia in 1909, one of the sessions on Sept. 29 was devoted to a symposium "Looking to the Increased Knowledge of Cancer." At this session a series of ten affiliated papers on various aspects of the topic of cancer was presented, and these papers were published in the issue of the *Pennsylvania Medical Journal* for November of that year. As a result of this meeting and of the growing realization of the profession of the steadily increasing prevalence and menace of cancer, the Pennsylvania Medical Society appointed a commission on cancer to study and investigate the subject and to report on methods of education in the prevention and control of the disease. The chairman of this commission was Dr. J. M. Wainwright of Scranton, Pa.

At the session of the Pennsylvania Medical Society in Harrisburg in September, 1911, this

commission presented a report, detailing the progress of its work up to that time.

"The principal work in connection with public education has been the preparation of a series of six short articles giving the information that the laity should have concerning cancer in various portions of the body. These will be sent to all the leading newspapers in the state with the hope that beginning next month all the newspapers will publish one article simultaneously each week.

"The most elaborate work that the Commission has undertaken has been the gathering of statistics during the past year that indicate as nearly as possible the condition in which the cancer patients come to the surgeon. Four hundred reports were received from surgeons all over the state, and while the total number is not large the very wide distribution of the source makes the summary of these statistics of considerable value, and tables giving the more important facts are printed herewith.

"Of these cancer cases 146 were males, 236 females, the remainder unspecified. The average age for the entire number was 51 years. A further analysis of these statistics can best be made by dividing the total number into superficial cancers and deep-seated cancers. The first striking result of this tabulation is that even in the superficial cancers only 68% are operable when the patients come to the surgeon, and of the deep-seated cancers only 48%, or less than one-half, are operable when they come to the surgeon. Furthermore, even these figures are undoubtedly much lower than the actual facts. This is because nearly every busy surgeon will see many cases in consultation or in the admitting room of a hospital that are so clearly inoperable that he returns the patients at once to their family physician or passes them along to someone else for palliative treatment and does not stop to make any record. The surgeon's records, therefore, are made up mostly of cases on which he does operate, and most of the other cases do not come to record at all. Even setting aside this source of error it is a distressing fact that only 68% of superficial cancers and only 48% of deep-seated cancers are operable when the patients come to the surgeon.

"Another important fact derived from these reports is that in 39% of the superficial cancers and in 46% of the deep-seated cancers there has been a precancerous condition or a chronic irritation. In other words, in almost one-half of the patients that are sent to the surgeon with a fully developed cancer, there has been a previous condition which might have been cured and cancer might not have developed."

Following the statement of the commission there appeared in the report a paper by Dr. Longnecker on "Some Considerations of the Cancer

Problem"; and a further one by Dr. William L. Rodman, now president of the American Medical Association, on "The Early Diagnosis of Cancer." In conclusion the report stated that the reasons for undertaking this collection of data were, first, to convince everyone that "the only efficient treatment we now have for cancer is nearly always so far delayed that its real benefit reaches a comparatively small number; the much larger number are needlessly sacrificed. We believe that the reports as tabulated above demonstrate this beyond the need of further argument. Secondly, this work was undertaken to show if possible just where the greatest responsibility lies. It is, of course, to be proportioned to the medical profession on the one hand and the general public on the other. There is the greatest possible room for improvement in both, but of the two it would seem that the medical profession should show a marked improvement first. We cannot view with complacency the fact that, as a general average, cancer patients have been under the care of their family physicians for over a year before they applied for a radical cure. We believe that this state of affairs is somewhat of a reproach to the medical profession and we believe that we have indicated that after-commissions will find their most useful work in improving the general attitude of the medical profession itself towards cancer."

For five years the cancer commission of the Pennsylvania Medical Society has actively continued the work thus begun and has published from time to time reports of progress and papers bearing on different aspects of the subject. Finally in January of this year the society formulated a plan to extend this work by securing the coöperation of medical journals throughout the United States, each of which should publish in July a special issue devoted wholly or in part to topics connected with cancer. Seventy-three periodicals accepted this invitation and agreed to enter into the plan; and the present issue of the JOURNAL represents its contribution towards this movement.

As a leading article we present an address prepared for delivery by Dr. Edward Reynolds of Boston at the annual meeting of the Massachusetts Medical Society last month. In this article Dr. Reynolds emphasizes some of the newer views of cancer and their present relation to the responsibility of the practitioner. It is significant that of the four other special

articles on cancer which compose the remainder of this issue, three deal with different aspects of cancer of the uterus. This selection was an intentional point of emphasis, since this form of cancer is not only numerically the most frequent but is practically the most preventable of all types. A very large proportion of cancers of the uterus originate in neglected and unrepaired lacerations of the cervix. Habitual care and timely repair of all such lacerations would practically eliminate such cancers of the uterus, leaving only those originating in the body or fundus. This, of course, can be made possible only by the education of the public to an appreciation of the danger and preventability of cancer of the cervix and education of the profession to an appreciation of the importance and the proper methods of observation and treatment of the lacerated cervix.

At the beginning of his address Dr. Reynolds calls attention to the work of the American Society for the Control of Cancer during the past two years. This Society has recently made a special study of cancer conditions in New England, a region in which cancer is more prevalent, especially among the older Yankee families, than in any other part of the country. The Society has recently issued as a circular an abstract from the *Quarterly Bulletin of the New Hampshire State Board of Health* for January, 1915, containing a review of cancer in that state, together with admirable advice to the public in regard to the necessity of early recognition and operative treatment. The article in which this review is presented is by Dr. Irving A. Watson, secretary of the New Hampshire State Health Department.

"Dr. Watson reviews the statistics of cancer in New Hampshire from 1884 to 1913, and shows that there has been a steady increase in the number of recorded deaths from 210 in the first year to 453 in the last year of that period. The total number of deaths from cancer for the entire period of thirty years was 9096. Of this number 3075 were males and 6021 were females. During the period reviewed the cancer death rate in New Hampshire increased from 5.93 to 10.42 per 10,000 of the population. Some people hold that much of the apparent increase of cancer is due to more correct diagnosis and better certification and statistics, but Dr. Watson does not believe that these factors can alone account for the increase of the disease in New Hampshire.

"The State Board of Health has therefore joined in the efforts which are now being made for the control of cancer by educational meth-

ods. The State Laboratory has also undertaken to assist the physicians in the early recognition of the disease by examining suspected cancerous material whenever submitted.

"The American Society for the Control of Cancer has undertaken to conduct a national campaign of education in regard to this disease, following the example and methods of the campaign against tuberculosis. The National Society is coöperating with state and local boards of health, medical societies, women's clubs, and other organizations in order to disseminate the latest knowledge about malignant disease. If the people of New Hampshire would carefully read and take to heart the sound advice given by the State Board of Health it may well be expected that the mortality from cancer in New Hampshire will begin to show a decrease."

In another column of this issue of the JOURNAL we publish a further statement by the secretary of the American Society for the Control of Cancer on "The Organization of National and Local Forces in the Campaign against Cancer." This statement presents most effectively the methods suggested and in part actually adopted by the Society in its work thus far, and should emphasize to readers the importance of organized efficiency and coöperation in dealing with this problem of public health.

Finally, in a communication from Dr. William Seaman Bainbridge of New York, we record what is perhaps the best summary that has appeared of the tenets to be enjoined in the dissemination of education on the subject of cancer. Above all, it should be remembered that this education needs to be equally of the profession and of the public, making the one capable and the other willing to perform its part in this movement for the prevention and control of one of the most relentless and inexorable scourges of mankind.

THE DUCTLESS GLANDS AND DIABETES.

THE relationship of the ductless glands to diabetes presents an interesting and instructive problem. The liver is concerned with sugar metabolism, the sugar being stored in the liver as glycogen when there is an over-supply of sugar in the body. If the supply of sugar is lowered or there is no intake or there is an over-use—in other words, when for one reason or another, the demand is greater than the supply—the liver cells proceed to produce sugar from proteids, and, in rare cases, even from fats. It

must be remembered, however, that the formation of sugar in the liver is controlled by the nervous system, certain ductless glands and their hormones. The rôle of the various endocrine glands is being understood. This subject is taken up in an interesting manner by Croftan (*Illinois Medical Journal*, Vol. xxiii). A review of the most important facts may here be given.

The pancreas inhibits the conversion of glycogen into sugar and its supply to the body, so that underactivity or absence of activity of the pancreas from any cause, disease or experiment, causes hyperglycemia and glycosuria, with the breaking down of proteid and fat to sugar, which is at once discharged into the system. The adrenal glands stimulate the conversion of glycogen into sugar, and therefore have an action antagonistic to the pancreas. As proof we may mention that adrenalectomy is followed by hypoglycemia; in Addison's disease sugar tolerance is high and adrenalin glycosuria (from experimental injection of adrenal) is almost impossible. The thyroid gland stimulates adrenal activity, but it is antagonistic to the pancreas. For example, thyroidectomy leads to increased sugar tolerance and absence of adrenalin glycosuria due to hyperfunction of the pancreas; in myxedema there is increased sugar tolerance and absence of adrenalin glycosuria, while in thyroid feeding and in Basedow's disease there is decreased sugar tolerance and even glycosuria. That the parathyroids inhibit thyroid activity seems to be proved by the fact that there is reduced sugar tolerance and easily produced adrenalin glycosuria following parathyroidectomy; no glycosuria occurs after pure thyroidectomy, but when the parathyroids are removed in addition to the thyroids hyperglycemia and even glycosuria soon appear. The pituitary or hypophysis is antagonistic to the pancreas, but it is overactive in adrenal hyperfunction and in thyroid hypofunction. We find, for example, glycosuria to be common in acromegaly, whereas the sugar tolerance is increased in Fröhlich's adiposo-genital dystrophy.

From the work done in this field and from the results obtained, Croftan justly concludes that the ductless glands are intimately related to carbohydrate metabolism. Furthermore, the sympathetic nervous system directly or indirectly through the adrenals (which are parts of the "chromaffin system" scattered through the sympathetic nervous system) seem largely to govern these activities, as proved by experiments

with piqure, which acts centrally on the sympathetic apparatus, and adrenalin, which acts peripherally on the sympathetic apparatus. It has also been found that where the ductless glands inhibit or stimulate, there is a reversibility of action, so that the two glands antagonize or enforce one another mutually. It may be asserted, as Croftan says, that "the whole process is concerned with establishing and maintaining under widely varying conditions the balance that must normally exist between the autonomous and sympathetic nervous system in order that the somatic processes of life may be properly carried out." From the curative standpoint Croftan does not believe that the administration of gland products promises much for the future, since, after all, it is but temporary substitution therapy. He admits that grafting of deficient gland elements or removal of hyperfunctioning glands are possibilities.

RECENT MEDICAL MEETINGS.

DURING the past month there has been an unusually large number of medical meetings in the United States, especially in California in conjunction with the Panama-Pacific Exposition. Most notable of these were doubtless the meetings of the American Medical Association and of the Pan-American Medical Congress. In conjunction with these there also assembled in San Francisco the following non-affiliated societies during the month of June: the Pacific Coast Oto-Ophthalmological Society, June 14 to 16; American Society of Tropical Medicine, June 14 to 16; American Association of Medical Milk Commissions, June 17 to 19; American Climatological and Clinical Association, June 18 and 19; American College of Surgeons, June 21; Medical Society of the State of California, June 21; American School Hygiene Association, June 25 and 26; American Association of Medical Examiners, June 21; American Therapeutic Society, June 21 and 22; American Proctologic Society, June 21 and 22; American Hospital Association, June 21 to 25; Medical Association of the Isthmian Canal Zone, June 23 and 24; Pacific Association of Railway Surgeons, June 25; American Academy of Medicine, June 25 to 28.

At the opening session of the sixty-sixth annual convention of the American Medical Association

on June 22, the principal address was delivered by the president-elect, Dr. William L. Rodman of Philadelphia on "Safeguards for Surgery," describing particularly the work and aims of the American College of Surgeons. Among the various section meetings one of the most important was that of the section on surgery on June 25, which was devoted to a symposium on military surgery. It was voted to hold the next meeting at Detroit, Mich., in 1916. Dr. Rupert Blue, surgeon-general of the United States Public Health Service was elected to succeed Dr. Rodman as president next year.

The fortieth annual meeting of the American Academy of Medicine was held in San Francisco from June 25 to June 28, inclusive. At the opening session on June 25 the presidential address was delivered by Dr. Woods Hutchinson of New York on "The Physician as a Pioneer"; and the annual address by Mr. David Starr Jordan on "The Relation of Medicine to the Peace Movement." The general subject of the entire meeting was "Medicine in Its Relationships to Commerce and Transportation." In this connection Dr. W. C. Rucker, assistant surgeon-general of the United States Public Health Service, presented an address on "The Transmission of Typhoid Fever on Trains and Steamboats"; Dr. Henry B. Hemenway of Evanston, Ill., on "The Transportation of Consumptives"; and Dr. C. W. Hopkins of Chicago on "The Hospital Organization of Railway Systems." Dr. Rupert Blue, surgeon-general of the United States Public Health Service, was elected an honorary member of the Academy. In his presidential address Dr. Hutchinson spoke in part as follows of the function of the physician in the development of new communities:

"The real enemy of the pioneer, the chief obstacle to the spread of civilization is not Indians, or wolves, or rattlesnakes, or even famine or flood, or winter cold or tropic heat,—but insects. Most schemes of colonization that failed—failed not from famine or the attack of enemies, but through disease. And more than half of them from one disease—malaria. This is not merely the Age of Man, but the Age of Insects, geologically considered, and the battle is to the death between them for the possession of the earth.

"In the tropics, the insects get the whip hand of man and keep him stupid, short-lived, uncivilized. It was the Plague of Flies, the bloody tyranny of insects, that drove man out of the warm, comfortable, fertile tropics into the chilly, rain-swept, half-the-year-frozen north. Now grown to full human stature, he is coming back

to invade and reconquer the tropics and put to flight the ancient foes of the race.

"In an earlier day the first requisite of a new colony for a pioneering expedition was a captain, bold and skilful fighting man, with muskets for every grown man in the party, and plenty of powder and ball. But now the first and most fundamental requirements of a new colony are a motor-engineer, with microscope and test tubes, ladders and trenching machines, and plenty of quinine, kerosene and mosquito netting.

"New countries can and ought to be models of health, efficiency and comfort for the older communities, and could easily be made so at moderate expense if the physician pioneer be given a free hand in advance, as Gorgas was at Panama. In fact, we can pretty nearly assure success if the soil be good and the water sufficient.

"It must be remembered in fairness that bad insects are, they do not originate the diseases they spread, but only carry them from one infected human being to other healthy ones. Deprive them of their source of infection and they become comparatively harmless. A few weeks' isolation or appropriate treatment with quinine, iarsan, thymol, etc., would be sufficient in the vast majority of cases to clear up all risk. Physical examinations would be worth twice their cost to the individuals examined alone; and, in combination with a proper sanitary survey, turn new countries and new colonies to little health-heavens on earth."

The next session of the American Academy of Medicine will also be held at Detroit, Michigan, in 1916, and its general topic will be "Legislation and Medicine."

The seventy-first annual meeting of the American Institute of Homeopathy was held in Chicago from June 28 to July 2, inclusive, and was attended by members from all parts of the United States. In conjunction with this meeting the National Society of Physical Therapies held its twenty-second annual session on June 30. Among the papers presented was one by Dr. James Seanson of London, a British surgeon attached to the Anglo-American Homeopathic Hospital in Paris. At the session of the institute on July 1 Dr. Henry C. Aldrich of Minneapolis was elected president for the ensuing year and it was voted to hold the next annual meeting at Baltimore. The following are the remaining officers elected:—

First vice-president, Dr. T. E. Costain, Chicago; second vice-president, Dr. Cornelia Brant, New York; treasurer, Dr. Thomas Franklin Smith, New York; secretary, Dr. Sarah M. Hobbs, Chicago; registrar, Dr. M. D. Forbes, Hot Springs, Ark.; trustees, Dr. E. M. Dearborn,

New York; Dr. J. Richey Horner, Cleveland; Dr. Byron E. Miller, Portland, Ore.

Particular attention was devoted at one of the sessions to the therapeutic value of tincture of alfalfa as a remedy for indigestion and mental depression.

MEDICAL NOTES.

HONORARY DEGREE FOR DR. STILES.—In last week's issue of the JOURNAL we noted the conferring of the honorary degree of doctor of science by Yale University on Dr. Charles W. Stiles. In conferring this degree the president said: "Five years of foreign study, arduous research and the spur of visible suffering have fitted and impelled Dr. Stiles to attack the obscurities of parasitic disease. Both brutes and men owe him gratitude. He is the discoverer of the American hookworm, that widespread and dreadful scourge of the South. By his investigation and through his propaganda an entire people is being lifted to a higher plane of physical and economic being."

PREVALENCE OF MENINGITIS, POLIOMYELITIS, SMALLPOX, AND TYPHOID.—The weekly report of the United States Public Health Service for June 25, 1915, states that during the month of May, 19 cases of cerebro-spinal meningitis and five of poliomyelitis were reported in Massachusetts. During the same month there were 115 cases of smallpox in Minnesota and 101 in Wisconsin. There were also 129 cases of typhoid fever in Massachusetts, 74 in Maryland, 54 in New Jersey and 35 in Minnesota.

CONSTITUTIONALITY OF THE HARRISON LAW.—Report from Chicago states that before the United States District Court a suit has been entered against a physician charged with aiding drug habitués to procure morphia and cocaine in violation of the Harrison anti-narcotic law. It was argued before Judge Landis by the council for the defendant that this law is unconstitutional because it denies the drug users their inalienable right to the pursuit of happiness.

MORTALITY RATES IN THE WESTERN HEMISPHERE.—Statistics of death rates from principal causes have been drawn up by the Prudential Insurance Company covering sixteen leading cities of North and South America. The diseases causing the largest percent. of deaths in these respective cities of North America are as follows. Except as otherwise stated, the figures cover the years 1908 to 1912.

Montreal—Diarrhea and enteritis.....	21.8
Winnipeg—1910-1912—Diarrhea and enteritis..	13.1
Vancouver—1911-1913—External causes.....	11.5

Boston—Pneumonia.....	11.5
New York—Pneumonia.....	13.6
Washington—Tuberculosis.....	13.4
Chicago—Pneumonia.....	14.2
Denver—Tuberculosis.....	20.8
San Francisco—Organic heart diseases.....	13.5
Los Angeles—Tuberculosis.....	18.4
New Orleans—Tuberculosis.....	12.9
Havana, Cuba—Tuberculosis.....	17.6
Kingston, Jamaica—Diarrheal diseases.....	13.3
Mexico City, Mexico—Diarrhea and enteritis.....	23.3
San Salvador, Salvador—Diarrhea and enteritis.....	16.7
City of Panama, Panama—Diarrhea and enteritis.....	19.5

LONDON DEATH-RATES IN MAY.—Statistics recently published show that the total death-rate of London in May, 1915, was only 14.6 per 1000. Among the several districts and boroughs, the highest rate was 23.1 in the central portion of the city, and the lowest was 11.1 in Wandsworth on the south.

DECLINE OF THE FRENCH AND BRITISH BIRTH RATE.—In previous issues of the JOURNAL we have called attention to the probability of an acceleration in the decline of the European birth rate as a result of the present war. Naturally this effect is now beginning to make itself felt with increasing obnoxiousness. During June the number of births in London alone was nearly 500 less than that of the corresponding period during the past five years, and a similar ratio of decline prevails elsewhere in Great Britain. Moreover, during the past quarter the number of deaths among infants has been 200 a week more than during the corresponding period of 1914.

Report from Paris on July 1 states that the decline in the French birth rate has been particularly noticeable during the current year. The rate in 1914 averaged 1000 births daily, but at the beginning of 1915 the figures dropped to 850, and there has been a rapid decline since then. In the week of June 6 to June 12, which was the last week recorded, there were only 356 births in the entire country.

EUROPEAN WAR NOTES.—During the period from Feb. 14 to May 20, 1915, there were reported in Europe 232 cases of typhus fever in Egypt, 240 in Germany and 833 in Moscow. From August 1, 1914 to April 24, 1915, there were 5489 cases of the disease in Austria-Hungary.

Report from London on July 2 states that the parliamentary under-secretary of war recently presented to the House of Commons statistics confirming the remarkable efficacy of antityphoid inoculation in the prevention of disease among the British troops.

"In the British expeditionary force in France there had been only 827 cases and 128 deaths up to May 27. Of this number 308 cases were per-

sons who had not been inoculated and 106 of these died. There were only 22 deaths among the 308 men inoculated who, despite inoculation, contracted the disease."

Report from Madrid by way of Paris on July 5 states that the pharmaceutical college of Spain reports an acute shortage of drugs in that country on account of the withdrawal of the source of supply of many important drugs produced in Germany.

On June 12 a surgical unit from the University of Pennsylvania sailed from New York aboard the steamship *St. Louis* for France, to assume charge of a ward in the American Ambulance Hospital at Neuilly, Paris. The personnel of this unit consists of ten surgeons and four nurses, the former being Dr. J. William White; Dr. James P. Hutchinson, who will be the managing head of the unit; Dr. Daniel J. McCarthy, neurologist; Dr. Edmund B. Piper; Dr. Walter Estell Lee; Dr. Arthur E. Billings; Dr. Peter M. Keating; Dr. Samuel Goldschmidt, bacteriologist; Dr. Thomas C. Aller and Dr. David M. Davis, of Johns Hopkins University. The period of service of this unit will be three months, beginning July 1.

On July 10, the total of the principal New England relief funds for the European War reached the following amounts:—

Belgian Fund.....	\$265,114.25
Red Cross Fund.....	135,955.10
Jewish Fund.....	64,737.27
Serbian Fund.....	34,121.19
St. George's Fund.....	10,517.69

It is reported by cable that the second Harvard surgical unit, which sailed from New York on June 25, has safely reached Falmouth, England, and has proceeded thence to London.

ROCKEFELLER WAR RELIEF COMMISSION.—The recently published report of the War Relief Commission of the Rockefeller Foundation describes the work of that organization among noncombatants in Europe since November, 1914. This investigation covered the entire field of the war with the exception of Turkey and Italy. The suffering and destitution were exaggerated in Serbia and Montenegro by the epidemic of typhus, which has now been largely checked by the work of the American Sanitary Commission under Dr. Richard P. Strong. Suffering is now most acute in Russian Poland and in part of Galicia. In its relief work in Poland the commission has been particularly aided by the cooperation of the German government, a cooperation which the report describes in part as follows:—

"The German government agreed to furnish \$500,000 a month for the purchase of food, and to stop all requisitions in Poland, as soon as the relief work began. Efforts to obtain grain from other countries in Europe for shipment to Poland were, however, unsuccessful. That sit-

ation has now been taken care of, as the German government has recently advised the commission that, having completed an inventory of the food supplies available at home, Germany found itself in position to assume entire responsibility for the relief of that part of Poland under its control. The commission for relief in Poland then restricted its attention to efforts in the district controlled by Austria, namely, southern Poland and Galicia. There, again, the greatest difficulty was experienced in obtaining grain from outside, but work has now just been completed that the work initiated by the international commission in that territory will be assumed by the National Austrian Committee."

The headquarters of the Commission has now been established in Switzerland, where it will continue its work throughout the war.

EFFICIENCY OF THE GERMAN RED CROSS.—In a recent issue of the American Red Cross monthly magazine is an article by Dr. Kimmle, secretary of the German Red Cross organization, describing the work of the German Red Cross during the present war. The German Red Cross was mobilized simultaneously with the army in 1914 and at present has over 5000 nurses in the field. "The nurses of the German Red Cross are divided into three classes, the first being the Red Cross Sisters, who for years have carried on the profession of nursing. Second class, the volunteer auxiliary sisters, who undergo one-half year's training, pass an examination, and who are called out from time to time to take part in competitive courses and practical service in military hospitals. The third class comprises the volunteer helpers of the Red Cross. They are employed only in the home military hospitals, and even then only under the supervision of trained nurses.

"Over 60% of the Red Cross nurses, about 500 in all, are now on the battlefield or in the field, war, and base hospitals. The remainder are at home, nursing not only sick and wounded soldiers, but also men, women and children of the civil population.

"Beside the female personnel, we have a male staff of stretcher bearers and sick attendants. They receive their training in the First Aid Detachment of the Red Cross and the Red Cross Association of Voluntary Attendants, as well as a number of the Samaritan Societies of the Red Cross. At the beginning of the war these organizations numbered from 70,000 to 80,000 men, and this number has materially increased.

"They are uniformed and equipped according to regulations, and form an army of 'Caritas.' About 20,000 men have been sent to the front or base, where they do service in army hospitals and in the depots, while a still larger number do service in army hospitals and Red Cross trains and the home military hospitals.

"We have army, Red Cross and auxiliary hospital trains and ambulances, these last being

complete ambulatory field hospitals, with all the comforts that a stationary field hospital affords its patients. The War Department hospital trains, classified by numbers, and the Red Cross trains, classified by letters of the alphabet, are about the same. They consist of fourth-class vestibule cars, that allow the physicians and nursing corps to get quickly and easily from one end of the moving train to the other. The wounded lie on stretchers, on which, in the Red Cross trains, are mattresses, and are protected from cold by blankets enclosed in washable linen cases. Ten such hospital trains the central committee of the Red Cross had completed shortly after mobilization, and there are now in the entire organization of the Red Cross several dozen.

"Besides aid to the sick and wounded, the Red Cross undertakes the duty of doing everything necessary for the families of the men called to arms. The state grants do not wholly cover all needs. The women of the Red Cross have tried to embrace in their grasp all those who require additional aid and care for them with self-sacrificing devotion and broad understanding."

BOSTON AND NEW ENGLAND.

RABIES EPIDEMIC IN MASSACHUSETTS.—On account of the prevalence of rabies in dogs throughout various cities and towns of this state quarantines have been declared in Cambridge, Belmont, Waltham, Gloucester, Rockport and Sterling, and precautionary measures have also been taken in Dedham. These quarantines were put into effect at the request of Dr. Lester H. Howard, commissioner of the Bureau of Animal Industry, and it is reported that he will ask for a continuance of the quarantine in Wakefield. The State Board of Health has on record twelve persons who are undergoing the Pasteur treatment for rabid dog bites. Fortunately the city of Boston so far has escaped the epidemic. Records show that only three cases of rabies have occurred in Boston this year and those occurred some time ago. On July 2 it was reported that all dogs in the town of Northbridge, Mass., are to be either leashed or muzzled on account of a dog who recently developed rabies in that town after being bitten by a stray dog. No one, so far as is known, was bitten by the animal.

CASE OF PELLAGRA IN WALTHAM.—On July 1 a case of pellagra was reported in Waltham, Mass., in the person of a woman formerly a resident of Newton. The diagnosis has been confirmed and the patient transferred to a state institution for treatment.

DECREASE OF BOSTON MARRIAGE RATE.—During the month of June, 1915, there were in Boston 140 fewer weddings than during the same period in 1914. During the first six months of this year there were in this city only 4638 mar-

riages as compared with 4985 during the first half of 1914.

TRANSFER OF MEDICAL INSPECTION OF SCHOOLS.

—In a previous issue of the JOURNAL we noted the proposal to transfer the function of the medical inspection of schools in Boston from the health department to the school department. On June 8 the Boston Board of Health passed the following vote:—

"It was voted by Messrs. Mahoney and Mulowney that the Board of Health shall on and after the first day of July, 1915, maintain no longer the medical inspection of the children in the public schools of the city, as the school committee has voted to exercise the powers and to perform the duties provided by law for the appointment of school physicians, and for the maintenance of such medical inspection."

This action is being contested by the school physicians to whom a hearing was given by the Board of Health on July 2, their chief objection being the proposition of the school committee to reduce the number of school physicians from eighty to forty. The Board of Health has issued a statement upon the subject, reading in part as follows:—

"The school committee by Chapter 357 of 1907 is required to appoint a supervising nurse and district nurses; these nurses by Section 1 of this chapter are to assist the medical inspectors in their work in the public schools. The school committee is allowed 2% on every \$1000 of the valuation upon which the appropriations of the City Council are based to meet the expenses thus incurred—roughly speaking, \$30,000. Such division in the charge and control of the work of medical inspection of public school children by having the school committee appoint the nurses and by having the Board of Health appoint the school physicians seemed to the Board of Health unnecessary and to result in less efficient service than if the complete authority over the subject were reposed in one department.

"The Board of Health has been unable to secure jurisdiction over the nurses, and now that the school committee has voted to take over the functions of medical inspection, believes that the best interests of the public require the Board of Health to relinquish such medical inspection."

COMPLIANCE WITH THE TUBERCULOSIS DISPENSARY LAW.—In previous issues of the JOURNAL we have commented from time to time upon the progressive compliance of the various cities of this Commonwealth with the law requiring the establishment of local dispensaries for the diagnosis of tuberculosis. It is stated by the Massachusetts Commissioner of Health that this compliance is now rapidly progressing.

"There are fifty-four cities and towns in Massachusetts of more than 10,000 inhabitants that come within the scope of the law and twenty-nine of them have already established dispensaries which have received the approval of the

State Department of Health. These are Boston, Worcester, Fall River, New Bedford, Springfield, Lawrence, Somerville, Malden, Haverhill, Salem, Newton, Brookline, Northampton, Leominster, Attleboro, Peabody, Woburn, Newburyport, Gardner, Marlboro, Clinton, Milford, Framingham, Watertown, Southbridge, Webster, Methuen, Arlington and Winthrop. In some instances, notably Malden and Winthrop, it is the intention to make the scope of the dispensaries even greater than the law requires. They will be housed in separate buildings and will be known as public health dispensaries. They will be headquarters for work looking toward the elimination of conditions which are favorable to tuberculosis and other diseases.

In addition to the twenty-nine places that have already complied with the law, fifteen others have provided dispensaries or have voted the money for them, and their arrangements probably will receive the approval of the state department within a short time. Included among these are Lowell, Cambridge, Taunton, Quincy, Gloucester, Chelsea, Pittsfield, Waltham, Chicopee, North Adams, Revere, Adams, Weymouth, Plymouth and Wakefield. This leaves only ten other cities or towns that are not immediately in line with the law."

MASSACHUSETTS HOSPITALS FOR CONSUMPTIVES.—The recently published eighth annual report of the Trustees of the Massachusetts Hospitals for Consumptives covers the four institutions under the control of that board, the North Reading, Lakeville, Westfield and Rutland Sanatoria. At the North Reading Sanatorium during the past year the daily average of patients has been 195 as compared with an average of 190 last year, and an original capacity of 150. Additions were made to the Lakeville State Sanatorium which increased the capacity of the hospital by 34 beds and the daily average of patients was 245. At the Rutland State Sanatorium the daily average of patients was 350. The admissions were 469 and the discharges 476. The daily average of patients at the Westfield State Sanatorium was 234. The hospital is now caring for over 100 children twelve years of age and under. The importance of childhood infection is coming to be recognized as a most important factor in anti-tuberculosis work, and the board wishes to impress upon physicians and anti-tuberculosis workers throughout the state the absolute necessity of recognizing and treating tuberculous children if progress is to be made in combating the disease. It urges the study of infection in children and the necessity of making an early diagnosis. The bulk of the patients at present under treatment in the state sanatoria represent the result of infection contracted when children. It arouse interest in the importance of this subject the Board sent out to every registered physician in the state a letter calling attention to this subject.

TYPHOID FEVER IN MANSFIELD.—The recently published bulletin of the Massachusetts State Department of Health for April, 1915, contains a brief study of two outbreaks of typhoid fever occurring in Mansfield, Mass., within the past year.

"During the months of August, September and October, 1914, and March, 1915, there were 47 cases of typhoid fever reported to the Board of Health of Mansfield. For the six preceding years there had been but 3 cases, 2 in 1911 and 1 in 1913. In the recent outbreaks, which were six months apart, 29 cases were reported in 1914 and 18 in 1915, the majority of the patients being women and children.

Investigations were made during the fall outbreak and it was found that all of the cases were on the route of one milk dealer. On account of his fact, and of the explosive character of the outbreak, it was concluded that the infection was conveyed by milk. The dealer in question, who supplied about 160 families, was not a producer but purchased from five dairies in the neighborhood. No cases of disease were discovered at any of these farms. Unfortunately, no specimens of blood from any of the milk dealers involved were examined by the Widal test.

No more cases of typhoid fever occurred in the town until the first of March, 1915, when, in the course of ten days, 18 cases were reported. All of the patients taking milk from this dealer. The second outbreak was of the same character as the preceding. The milk supply from this dairy was shut off. Laboratory investigations were undertaken immediately. Widal tests were made of the blood from members of the family of the milk dealer and those selling to him. A positive Widal reaction was obtained from the blood of the child of the milk dealer and an typical reaction in the case of the wife. Typhoid bacilli were isolated from the urine of the child.

Considered epidemiologically, it seemed as if there were a common source of infection for these two outbreaks. There is the possibility that the milk dealer's wife and child, who visited Rhode Island in July, 1914, may have become infected there with typhoid and one or both become carriers."

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending July 6, 1915: Diphtheria, 55 of which 6 were non-residents; scarlatina, 49, of which 10 were non-residents; typhoid fever, 1; measles, 132; tuberculosis, 51, of which 2 were non-residents. The death rate of the reported deaths for the week was 11.77. Low though it is, this rate is slightly higher than that of the corresponding week last year. This is due partly to the increased incidence of diarrheal diseases of infancy during the recent wet weather, partly to the steady increase in deaths from cancer and cardio-renal degeneration.

Miscellany.

THE ORGANIZATION OF NATIONAL AND LOCAL FORCES IN THE CAMPAIGN AGAINST CANCER.

By CURTIS E. LAKEMAN,

Executive Secretary, American Society for the Control of Cancer.

THE American Society for the Control of Cancer has recently urged that every state medical society take an active part in arranging meetings and in spreading among all members of the profession the latest knowledge of malignant disease. At the suggestion of the Cancer Committee of the Pennsylvania State Medical Society, many journals will devote their July issues to this subject. It has been pointed out that the American Society for the Control of Cancer might take this timely opportunity to state its view of the relations between the various bodies which are concerned in this campaign. The suggestion is welcome. If, indeed a clear understanding can be reached as to the most effective division of functions and duties among the various organizations, national, state and local, interested in this subject, a long step will have been taken toward the conquest of malignant disease, in so far as that ideal can be approached by the practical application of present knowledge.

The National Society. The American Society for the Control of Cancer sets up no claim of priority or originality in preaching to the public the necessity of early recognition and treatment of this disease. The organization was effected under the inspiration of numerous similar movements in this country and in Europe. From the first it has been inspired only by a sincere ambition to coördinate all existing forces into a single irresistible nation-wide effort to reduce the cancer death rate by imparting the necessary knowledge and inspiring the will to believe and act upon it. Those who direct the policy of the Society have no illusions that they are "called" above others to this task. They firmly believe that all sincere workers should unite in a single well considered national movement. If the present Society fails to meet the requirements of such a movement it must give place to some agency that will do so, leading the campaign against malignant disease with as conspicuous ability and success as the National Association for the Study and Prevention of Tuberculosis has directed the war on consumption.

Relation to the Professional Societies. While the Cancer Society found its first impulse in the work of a committee of the American Gynecological Society, the movement was broadened at its very inception by the appointment of organizing delegates from the American

Surgical Association, the American Dermatological Association, the Association of Pathologists and Bacteriologists, and practically all the similar special organizations which met in Washington in May, 1913, as the Congress of American Physicians and Surgeons. Definitely launched in New York on May 22, 1913, the movement received within a few months the official endorsement of the American Medical Association, the Clinical Congress of Surgeons, the Western and the Southern Surgical and Gynecological Societies and a number of sectional and state organizations. All these professional bodies have endorsed the design of the National Cancer Society as expressed in its Constitution:—

“To disseminate knowledge concerning the symptoms, diagnosis, treatment and prevention of cancer, to investigate the conditions under which cancer is found and to compile statistics in regard thereto.”

Relation to Cancer Research. It will be seen that this purpose comprises not only the conduct of an educational campaign, but the gathering of information in regard to this disease. In what relation, then, does the Society stand to the various American cancer research institutions and workers? The answer is that the Society does not contemplate the prosecution or support of biological research, already so ably pursued under the auspices of our leading universities. With these workers in the field of pure science mutually helpful relations have developed. Indeed a notable collective expression of their attitude is regarded as a very cornerstone of the educational movement. A few years ago the eminent laboratory students placed on record in the transactions of their official organization, the American Association for Cancer Research, their conviction that pending the discovery of the ultimate nature and cause of cancer, a far more effective dissemination and utilization of the vast store of present knowledge of the disease is urgently called for. Formed to carry out this very object, the “Control” Society depends upon the constant support and co-operation of the institutions represented in the “Research” Society. Many of the foremost American students of cancer are prominent in the membership of both organizations. Machinery is thus provided for the wider dissemination among the profession and the people of the essence of the newest knowledge of malignant disease, fresh from its laboratory sources.

Relation to Statistical Investigations. The Society does, however, contemplate original work in the collection and collation of statistical data, and will expand this feature of its program as fast as its resources permit. The statistics of cancer mortality need to be improved both as regards their collection and their publication. The merest suggestion by the Society to the U. S. Census Bureau has been sufficient to initiate a notable advance in this respect. With the greatest possible interest and zeal, Mr. Har-

ris, the late Director of the Census, and his successor, Mr. Rogers, have undertaken the preparation of a special report on the cancer mortality of the U. S. Registration Area in 1914. The number of deaths will be stated in full detail under some thirty titles of organs and parts of the body affected, instead of, as hitherto, merely under the six general groups of the International List. The Imperial Cancer Research Fund has long urged that it is only on the basis of such detailed data for the various organs that a true conclusion can be reached as to whether or not cancer is increasing. For the first time in the United States the data will now be at hand, as it is in England and Wales, through the reports of the Registrar-General, for the prosecution of such inquiries.

The Census Bureau will also for the first time in this study make a distinction between returns based on certain and on doubtful diagnosis. To secure the additional information needed for this distinction the Bureau is sending tens of thousands of letters to physicians who have certified deaths from cancer asking whether the diagnosis was based on clinical findings alone or was established by surgical intervention, microscopic examination, or autopsy.

All this, it will be realized, is a large amount of work for even a government bureau to undertake. Much of it should be done in the first place by the registration offices and the boards of health of the several states, where the original certificates of death are filed. It will be the duty of the American Society for the Control of Cancer to urge upon the various state officials the need of undertaking this work in order to insure the permanence of the advance in the statistical study of cancer which has been inaugurated by the Census Bureau.

But the Society is also interested in special statistical studies of the geographical, racial and occupational distribution of cancer, and above all in collating, upon a uniform plan, the records of surgical treatment of the disease in the leading hospitals. It is important that an authoritative answer be available for all who ask just what percentage of success is to be expected in the treatment of each phase and each stage of this multiform disease. All such studies the Society regards as fulfilling its fundamental purpose and in pursuing them it is everywhere receiving the most cordial encouragement and assistance from statistical offices and from the best hospitals and institutions.

Relation to Educational Agencies. The important and clearly established lessons derived from such studies of the sources of information must be given to the public. The Society has undertaken to do this directly, through its publications, its regular articles for the news papers and its lectures. But in the large view it can best secure this object by enlisting the co-operation of all appropriate existing agencies which conduct educational work. Foremost

among these are the state and local departments of health, especially those which are devoting an increasing share of their energies to the spreading of the gospel of health by bulletins, exhibits and lectures. In the same category must be included the committees on public instruction, which in many states are conducting admirable campaigns of health education under the auspices of the state medical societies. Toward all these agencies the Society stands in the relation of the "producing" to the "distributing" end of a manufacturing business. With its wide outlook over the national field it is in a strong position to provide statistical material, to receive and pass on new knowledge, new experiences, new methods which have been found valuable in one field and should be used in others. In another view the Society may take the position of "middleman" between the research workers and statistical students, producing new facts about cancer at the sources of knowledge on the one hand, and on the other the many agencies, general and local, which will bring the practical bearings of this knowledge, new and old, directly home to the people. In general, then, one of the most useful functions of the Society is to act as a bureau of information and clearing house, which is at the service of all workers and institutions interested in the study and control of cancer.

Relation to State Committees. The relation of the National Society to similar movements within the various states should be clear from what has been said. In no case will the Society seek to set up local agencies to parallel work already adequately organized under the auspices of state medical societies and boards of health. Provision is made for local committees to be organized under the supervision of the resident directors of the National Society, wherever no state or local agency is in a position to undertake the work. Such groups will not be formed, however, except under full agreement with present state agencies. Where, as in Pennsylvania, under Dr. Wainwright, and similarly under the auspices of state medical societies in Maine, Wisconsin, Kansas, Colorado, Louisiana, Texas and many other states, active local committees are at work, every effort will be made to assist these groups in the manner already outlined and, so far as the constitutional limits of size permit, to secure from them representative delegates to the governing council of the National Society. At least one director from each state will eventually be chosen to act as a local correspondent who will inspire and stimulate work in his own state, while at the same time assisting in formulating the general policies of the National Society.

Relation to Other General Committees. It is an earnest of the good feeling and harmony with which the cancer campaign is evolving toward a single coherent national movement to consider the high degree of integration with other national agencies which has already been

attained. Some of these had begun effective work long before the present Society was established. Aside from such admirable local campaigns as that of the Pennsylvania Commission and the work inspired by Dr. C. C. Carstens in Michigan, the Clinical Congress of Surgeons of North America had in the field an active Committee on Cancer under the chairmanship of Dr. Thomas S. Cullen of Baltimore, the other members being Dr. Simpson of Pittsburgh and Dr. Howard C. Taylor of New York. This committee, as is well known, caused the publication of widely read and influential popular articles by Samuel Hopkins Adams. It is instanced merely as indicative of the get-together spirit that animates the National Society that all three of these men naturally took their places as members of the Executive Council of the new association. Subsequently the American Medical Association appointed a Cancer Committee representing its Council on Health and Public Instruction, and again, to avoid duplication of effort, the same men were made members of that committee. Dr. Frederick R. Green, the capable executive of this Council of the American Medical Association, has been from the first a director of the Cancer Society, and has given invaluable advice and cooperation in its publicity campaign, printing every week in the press bulletin of the A. M. A. a popular article on cancer prepared by the Society, which thereby reaches 3000 or more editors in all parts of the country.

A similar identity of committees has been effected in local fields, especially in Minnesota, and is typical of the desire to carry on everywhere a well-coördinated national campaign which shall embrace representation from all the principal local agencies and shall thus move forward with absolute harmony and unity of purpose to the accomplishment of its difficult but glorious ideal—the progressive reduction of the mortality from this historic scourge of mankind.

COMPARATIVE DEATH RATES.

The mortality statistics of the United States Census office for 1913 have recently become available and show that of the registration states Washington has the lowest death rate and disease incidence. The other registration states follow Washington in the subsequent order: Minnesota, Utah, Wisconsin, Colorado, Montana, Missouri, Kentucky, Indiana, Michigan, Ohio, Virginia, New Jersey, New York, Pennsylvania, California, Connecticut, Maine, Massachusetts, Rhode Island, Vermont, Maryland, North Carolina, New Hampshire.

The non-registration states in the union are the following: Illinois, Iowa, North Dakota, South Dakota, Nebraska, Kansas, Wyoming, Idaho, Oregon, Nevada, South Carolina, Georgia, Florida, Alabama, Tennessee, Missis-

issippi, Arkansas, Louisiana, Oklahoma, Texas, New Mexico and Arizona.

In these non-registration states the following cities belong to the registration area: Birmingham, Mobile and Montgomery, Ala.; Wilmington, Del.; Jacksonville, Key West and Pensacola, Fla.; Atlanta, Augusta and Savannah, Ga.; Aurora, Belleville, Chicago, Decatur, Evanston, Jacksonville, Quincy and Springfield, Ill.; Atchinson, Coffeyville, Fort Scott, Hinthinson, Independence, Kansas City, Lawrence, Leavenworth, Parsons, Pittsburgh, Topeka, Wichita, Kan.; New Orleans, La.; Lincoln and Omaha, Neb.; Portland, Ore.; Charleston, S. C.; Nashville and Memphis, Tenn.; El Paso, Galveston and San Antonio, Tex.; Wheeling, W. Va.

Compared with other nations the United States in 1912 stood sixth in the percentage of its death rate. The countries which surpassed it were New Zealand, Australia, Denmark, England and Norway. The remaining countries followed the United States that year in the subsequent order: Sweden, Scotland, Prussia, Switzerland, Belgium, Ireland, Finland, France, Italy, Austria-Hungary, Spain, Serbia, Roumania, Chili.

Within recent years the most rapid decrease in the death rate has taken place in Holland, Prussia and Australia.

In 1912 The Hague had the lowest death rate in the world, 10.9. Amsterdam stood second with a rate of 11.2 and the remaining large cities of the world followed in subsequent order: Rotterdam, Sidney, Toronto, Turin, Dresden, Christiana, Brussels, London, Hamburg, Melbourne, New York, Copenhagen, Stockholm, Berlin, Munich, Chicago, Philadelphia, Vienna, Edinburgh, Prague, Milan, Boston and Paris.

In 1913 Seattle had the lowest death rate among the large American cities, 8.4. Spokane stood second with a rate of 8.9, and Portland, Oregon, third, 9.5. The remaining cities followed in subsequent order: St. Paul, Minneapolis, Oakland, Milwaukee, Grand Rapids, Cambridge, Paterson, Omaha, Denver, Cleveland, New York, (14th, rate 14.3), Newark, Jersey City, Rochester, Scranton, Kansas City, Bridgeport, St. Louis, Los Angeles, Chicago (23d, rate 15.1), Providence, Columbus, Philadelphia, Syracuse, Indianapolis, Buffalo, Worcester, Lowell, New Haven, San Francisco, Dayton, Toledo, Louisville, Boston.

The negroes have a much higher death rate than any other nationality or race.

The rank of the cities in which the negro population is more than 20% is as follows: Portsmouth, Va., 13.7; Durham, N.C., 14.1; Key West, 14.9; Others come in the order named: Roanoke, Atlantic City, Charlotte, N.C., Pensacola, Newport News, Greensboro, Knoxville, Washington, Birmingham, Atlanta, Alexandria, Nashville, Frankfort, Ky.; Lynchburg, Danville, Va.; Jacksonville, Fla.; Norfolk, Augusta, Henderson, Ky.; New Orleans, Paducah, Rich-

mond, Va.; Memphis, Winston-Salem, Mobile and Ashville.

The average death rate for cities having a large negro population is 18.3.

In 1913 the lowest death rate from diphtheria in American cities was 0.8 in Spokane. Other figures were: 1.9 at Birmingham, Ala.; 4.4 at Seattle; 5.3 at Portland, Ore.; 6 at Richmond Va.; 36.3 at Cleveland; 36.6 at Pittsburgh; 41.2 at Chicago; 43.9 at Grand Rapids and 57.6 at Detroit. The lowest scarlet fever death rate in 1914 was 0.6 at Birmingham, Ala., and at New Orleans. Other rates were 1.1 at Oakland, Calif.; 2 at Albany and Seattle, 2.2 at Kansas City, 21.8 at Fall River, 22.3 at Denver, 26.4 at Pittsburgh, 26.8 at Bridgeport, Conn., and 39.2 at Chicago.

In 1913 the greatest prevalence of smallpox occurred in these states in the following order: North Carolina, Utah, Montana, Minnesota, California and New Hampshire. The greatest incidence of diphtheria was 25.9 per hundred thousand in Pennsylvania, the least was 3.1 in Washington. Next to Washington came Montana, California, Colorado, Utah, Vermont and Minnesota. The lowest incidence of scarlet fever was 2.2 in Maine, next in Washington, Kentucky, Virginia, North Carolina, New Hampshire and California. The rate in Colorado was 17.2 and the highest was 282.4 in Montana.

The tuberculosis incidence rate was lowest in Utah, 41.5. Washington stood second with a rate of 74.9. Other rates were Michigan, 77.4; Wisconsin, 84.3; Minnesota, 88; Vermont, 88.3; Montana, 93.3; Maine, 96.2; New Hampshire, 98.9; Pennsylvania, 104; Ohio, 113; Massachusetts, 120.8; Connecticut, 121; Indiana, 125; Missouri, 126.7; Rhode Island, 133.4; New Jersey, 134.1; New York, 145.9; Virginia, 149.6; Colorado, 170.6; Maryland, 174.6; California, 175.6; Kentucky, 176.2, and North Carolina, 203.8.

The typhoid incidence rate was lowest in Vermont, 7.8. Massachusetts stood second with a rate of 7.9 and the rates in other states were as follows:—Rhode Island, 8.3; Wisconsin, 9, and New Jersey, 9.6. North Carolina is at the bottom of the list with a rate of 57.4. Kentucky was second from the bottom with 42.7; Virginia, third, 33.3; Indiana, 25.1; Missouri, 24.4, and Ohio, 24.

Of infant death rates, from diarrheal diseases, the lowest was 21.6 in Washington. Montana stood next with a rate of 38.6 and in other states the rate was: Minnesota, 41.3; Utah, 43; Colorado, 43.2; New Jersey, 89.9; New Hampshire, 96.2; Maryland, 101.1; Pennsylvania, 106.3, and North Carolina, 114.4. Among the various cities, the lowest death rate from this group of diseases was 9.8 at Portland, Ore. Other rates are 10.2 at Seattle, 24.9 at Spokane; Denver, 24.3, and 31.7 at San Francisco. Among the high rates are 138.5 at Scranton, 142 at Chicago, and 142.3 at Buffalo. The two

highest rates occur in two Massachusetts cities, 165.6 at Lowell and 224.2 at Fall River.

Compared with the total number of deaths, the total number of infant deaths under one year of age in several cities was as follows: Of each 1000 deaths in the United States in 1913, 179 were children under one year of age. The proportion in San Francisco was 90 out of each 1000; in Denver, 114; Los Angeles, 115; Portland, 125; Seattle, 126; Spokane, 135; Boston, 177; Philadelphia, 180; New York, 186; Chicago, 199.

The relative frequency of deaths from various causes may be illustrated by the statistics in Chicago for 1913:

The largest group is deaths of children under one year of age from all causes, 6,939; second, pneumonia, all forms, 4,832; third, consumption, 3,430; fourth, heart disease, 3,337; fifth, bowel trouble in children under two years of age, 3,329; sixth, Bright's disease, 2,697; seventh, violent deaths, excluding suicide, 2,113; eighth, cancer, 2,017; congenital debility and malformation (in the newly born), 1,363; 10th, cerebral hemorrhage (apoplexy), 1,167; 11th, diphtheria, 965; 12th, scarlet fever, 918; 13th, cirrhosis of the liver, 527; 14th, suicide, 517; 15th, tuberculosis, other forms than consumption, 468; 16th, appendicitis, 389; 17th, diabetes, 375; 18th, measles, 278; 19th, typhoid fever, 243; 20th, hernia and other forms of obstructions of the bowels, 217; 21st, puerperal fever, 198; 22d, rheumatism, 183; 23d, bronchitis, 182; 24th, meningitis, 176; 25th, puerperal affections other than fever, 165; 26th, erysipelas, 109; 27th, influenza, 101; 28th, whooping cough, 84.

Among the larger American cities 23 had, last year, a typhoid death rate lower than 10. Of these the best standing was taken by Cambridge, Mass., with a rate of 1.8. Bridgeport, Conn., stood second with a rate of 3.4 and Worcester, Mass., third with a rate of 3.7. New York City stood eighth with a rate of 6.2, Chicago thirteenth with a rate of 7.1, Philadelphia fourteenth with a rate of 7.4, and Boston nineteenth with a rate of 9.1.

ARTICLES OF FAITH CONCERNING CANCER.

NEW YORK, N. Y., July 1, 1915.

Mr. Editor: The enclosed "Articles of Faith" concerning cancer were presented by me at several of the sessions during the four-day Cancer Educational Campaign, under the auspices of the Vermont State Medical Society, June 8-11, 1915. They concluded a paper entitled "The Cancer Patient's Dilemma. A Plea for the Standardization of What the Public Should be Taught in the Campaign of Education Concerning Cancer," which I read at one of the sessions, and which appears in full in the Cancer number of the *New York Medical Journal*, July 3.

Dr. Jonathan M. Wainwright, Chairman of the

Committee on Health and Public Instruction, Sub-Committee on Cancer of the Medical Society of the State of Pennsylvania, and a number of others who heard the paper or "Articles of Faith," have suggested that these Articles should be given wide circulation among the medical profession, as a platform, so to speak, upon which we can unite in teaching the public concerning cancer. They have urged that I send copies to the different medical journals for publication in the Cancer Number, or in the next issue.

In accordance with this suggestion, I am enclosing copy, to which I trust you will give space in your journal.

Yours very truly,

WM. SEAMAN RAINBRIDGE, M.D.

"ARTICLES OF FAITH" CONCERNING CANCER.

A PLATFORM UPON WHICH TO UNITE IN THE CAMPAIGN OF EDUCATION.

1. That the hereditary and congenital acquirement of cancer are subjects which require much more study before any definite conclusions can be formed concerning them, and that, in the light of our present knowledge, they hold no special element of alarm.

2. That the contagiousness or infectiousness of cancer is far from proved, the evidence to support this theory being so incomplete and inconclusive that the public need have no concern regarding it.

3. That the communication of cancer from man to man is so rare, if it really occurs at all, that it may be practically disregarded.

4. That those members of the public in charge of or in contact with sufferers from cancer with external manifestations, or discharges of any kind, need at most take the same precautionary measures as would be adopted in the care of any ulcer or open septic wound.

5. That in the care of patients with cancer there is much less danger to the attendant from any possible acquirement of cancer than there is of septic infection, or blood poisoning from pus organisms.

6. That in cancer, as in all other disease, attention to diet, exercise and proper hygienic surroundings is of distinct value.

7. That, notwithstanding the possibility of underlying general factors, cancer may, for all practical purposes, be at present regarded as local in its beginning.

8. That, when accessible, it may, in its incipency, be removed so perfectly by radical operation that the chances are overwhelmingly in favor of its non-recurrence.

9. That, when once it has advanced beyond the stage of cure, suffering in many cases may be palliated and life prolonged by surgical and other means.

10. That while other methods of treatment may, in some cases, offer hope for the cancer victim, the evidence is conclusive that surgery, for operable cases, affords the surest present means of cure.

11. That among the many advances in and additions to cancer treatment, the improvements in and extensions of surgical procedure surpass those in any other line, and fully maintain the preëminent position of surgical palliation and cure.

12. That there is strong reason to believe that the individual risk of cancer can be diminished by the eradication, where such exist, of certain conditions which have come to be regarded as predisposing factors in its production.

13. That some occupations, notably working in pitch, tar, paraffin, anilin or soot, and with x-rays, if not safeguarded, are conducive to the production of cancer, presumably on account of the chronic irritation or inflammation caused.

14. That prominent among these predisposing factors, for which one should be on guard, are: general lowered nutrition; chronic irritation and inflammation; repeated acute trauma; cicatricial tissue, such as lupus and other scars, and burns; benign tumors—

warts, moles, nevi (birth-marks), etc.; also that changes occurring in the character of such tumors and tissues, as well as the occurrence of any abnormal discharge from any part of body, especially if blood-stained, are to be regarded as suspicious.

15. That while there is some evidence that cancer is increasing, such evidence does not justify any present alarm.

16. That suggestions which are put forward from time to time regarding eugenic, dietetic and other means of limiting cancer, should not be accepted by the public until definitely endorsed by the consensus of expert opinion. Such consensus does not exist today.

17. That so far as we know there is nothing in the origin of cancer that calls for a feeling of shame or the necessity of concealment.

18. That it will be promotive of good results if members of the public who are anxious about their health and those who wish to preserve it will, on the one hand, avoid assuming themselves to be sufferers from one or another dreadful disease, but, on the other hand, will submit themselves periodically to the family physician for a general overhauling.

19. That at all times and under all conditions there is much to be hoped for and nothing to be feared from living a normal and moderate life.

20. That the finding of any abnormal condition about the body should be taken as an indication for competent professional and not personal attention.

21. That watchwords for the public until "the day dawns" and the cancer problem is solved, are: Alertness without apprehension, hope without neglect, early and efficient examination where there is doubt, early and efficient treatment when the doubt has been determined.

BELGIAN PHYSICIANS' RELIEF FUND.

REPORT OF THE TREASURER OF THE COMMITTEE OF AMERICAN PHYSICIANS FOR THE AID OF THE BELGIAN PROFESSION FOR THE WEEK ENDING JULY 3, 1915.

CONTRIBUTIONS.

APPOINTMENTS.

The Board of Scientific Directors of the Rockefeller Institute for Medical Research announces the following appointments and promotions:

Dr. James B. Murphy, hitherto an associate in the department of pathology and bacteriology has been made an associate member.

The following have been made associates:

Dr. Carrol G. Bull (pathology and bacteriology).
Dr. Frederick S. Jones (pathology and bacteriology).
Dr. Clarence J. West (chemistry).
Dr. Michael Heideberger (chemistry).
Dr. Frederick M. Allen (medicine).
Dr. Oswald T. Arvey (bacteriology).
Miss Angelica M. Courtney (chemistry).
Dr. Eduard Chlenkuth (experimental biology).

The following have been made assistants:

Dr. Harold K. Faber (pathology and bacteriology).
Mr. Chester H. Allen (chemistry).
Mr. James K. Senior (chemistry).
Mr. Glenn E. Cullen (chemistry).
Miss Mariam Vinograd (chemistry).

The following new appointments are announced:

Dr. R. Werner Marchand, assistant in the department of animal pathology.
Dr. Carl Ten Broeck, associate in the department of animal pathology.
Dr. Herbert D. Taylor, assistant in pathology and bacteriology.
Dr. Oswald H. Robertson, assistant in pathology and bacteriology.
Mr. Ernest A. Wildman, fellow in chemistry.
Dr. Reginald Fitz, assistant in medicine and assistant resident physician.
Dr. Arthur L. Meyer, assistant in physiology and pharmacology.

Dr. Robert M. Merrick, of Dorchester, Mass., has been appointed a member of the Massachusetts State Board of Charity.

RECENT DEATHS.

DR. VICTOR A. ELLSWORTH, who died of cardio-renal disease on July 5, at Boston, was born in Milford, N. Y., on April 20, 1846. He received the degree of M.D. in 1876 from the University of Buffalo, and after practicing for a time at East Otto, N. Y., removed to Boston, where in 1894 he became superintendent of the Washingtonian Home for Inebriates. He was a member of the American Medical Association, the New York State Medical Society, and the Massachusetts Eclectic Medical Society. He is survived by his widow, one daughter, and one son.

DR. JOSEPH REDFEARN, of Marlborough, Mass., died of apoplexy at his home on July 1, aged 66 years. He was a graduate of Harvard College, the College of Physicians and Surgeons of New York in 1873, and joined The Massachusetts Medical Society in the same year, practicing in his early days at Ashland, Mass. He also practised in Fall River, Hudson and Marlborough, Mass. He is survived by his widow.

DR. EDWARD MERRILL CURRIER of Brookline, Mass., who died of trauma in Quincy, Mass., on July 9, was born at Chelsea, Mass., in 1855. He received the degree of M.D. in 1881 from Boston University, and that of D.M.D. from Harvard in 1885. He is survived by his widow.

DR. CHARLES UPHAM SHEPARD, who died recently at Summerville, S. C., was born in New Haven, Conn., on Oct. 6, 1843. He obtained his preliminary education at Andover Academy and Yale College, and studied medicine at the University of Göttingen, Germany. He never practised his profession, but devoted himself to the study of chemistry of soils and fertilizers, and to the scientific cultivation of tea.

Address.

ALCOHOLISM.*

By ERNEST B. EMERSON, M.D., BRIDGEWATER, MASS..

Bridgewater State Hospital.

ALCOHOLISM has in all times involved the peace and prosperity of a large proportion of the human race. Ancient Egyptian inscriptions, Chinese manuscripts and the Old Testament note the use and abuse of wine and call attention to the evils of drunkenness. Its ravages have wrecked homes, brilliant intellects and empires. It has filled almshouses, hospitals and prisons; and misery has followed its wake. While it is true that the highest order of genius may exist among alcoholics, such genius is one-sided; the more common result is inefficiency, work half-done and the scrap heap for the habitué.

It is primarily a nervous disease, its effects on other organs being more or less secondary manifestations. All viscera are involved and the effects vary with the personal idiosyncrasy, the duration of the disease, and the amount taken. In one it may be the central nervous system, in another the kidneys or the liver which bear the brunt of its toxic action. In the beginning drinking may or may not be regarded as a vice, but at what period it becomes an unbreakable habit or disease only a wise man may say. The individual arrives at this point without knowing

it himself. With the continued use of alcohol there are certain developments and signs which definitely mark the drunkard. Many can drink in moderation without obvious harm, perhaps with no damage; but in some, as time goes on, changes take place modifying the mental and moral life, apparent to the nearest of kin, but unrecognized by the individual. Accompanying the mental and moral degeneracy visceral changes occur, and the kidneys, blood-vessels and liver become less efficient, rendering the drinker thereby even more susceptible to intellectual decay, and a poor subject to meet the crisis of pneumonia or any disease, requiring all that may be in reserve.

The brain is the physical organ presiding over the mind, and through its nerve connections controls the various functions of the body. Upon the integrity of the central nervous system depend all mental and physical phenomena, growth, nutrition, voluntary and involuntary movements, judgment, self-control, intellectual and moral characteristics. Physical or functional impairment of any part of this complicated system is manifested by more or less definite and characteristic evidence of disease. Motor and sensory areas have been charted so that it is possible to localize with a fair degree of accuracy the lesions producing physical dilapidation. The locations of intellectual, moral, judgment and self-control centers remain in the fog, although we are more or less familiar with their many manifestations. The integrity of such functions is necessary for a healthy mental life. The mind is dependent on a healthy condition of the brain, which, in turn, is to a

* Annual oration before the Plymouth District Medical Society at Brockton, Mass., April 15, 1915.

greater or less degree dependent on physical health. Intellectual and moral manifestations are directly influenced by any change from the normal equilibrium. Temporary impairment follows fatigue, injuries, toxic substances or changes in the circulation. Remove these causes, provided cell changes have not taken place, and the mind soon functions in its accustomed manner.

By tradition the laity and profession have long regarded alcohol as more or less of a cure-all, as well as a stimulant, but scientific research has demonstrated that its dominant influence is depressant and that its value as a drug has been far overrated. The effect of moderate and large doses is essentially one of degree, and varies in different individuals. In moderate or medicinal doses it has little effect on the pulse or blood pressure, but does change the distribution of the blood stream, as may be noted by the flushed face, due to dilation of the capillaries with a corresponding contraction of the vessels in the muscles and in the splanchnic region. It is probable that whatever good follows its use is due in large part to this change in the blood stream. Whether or not the immediate action of alcohol on the brain is a true stimulation or a depression of the inhibitory apparatus, the ultimate results leave little for debate. It is generally admitted, however, that mental vigor and energy are not increased and that the increased activity of thought is not due to a stimulation, but to a depression of the inhibitory apparatus.

Moderate doses produce a sense of well-being and exhilaration, with an increased flow of ideas and a loose tongue. With increased doses mental processes are enumbed, and the capacity for work is diminished, clear reasoning is impaired, and with increased amounts, judgment, self-control and the sense of responsibility are impaired and finally lost. Motor activity, and finally the power of speech disappear, drowsiness and coma complete the picture of alcoholic intoxication. Recovery, as a rule, takes place. Alcohol thus used over a sufficient period leads to more or less permanent impairment of the moral sense, powers of self-control and physical health; and with this damage continued debauches lead to that point where the drinker becomes little more than an irresponsible nuisance. A drunkard once made is held fast; the finer feelings and moral sense are blunted. He becomes mentally weak, excitable and quarrelsome, with a tendency to outbursts of rage and violence. In his sober moments he is indolent, neglectful of duty, and indifferent to his family and social relations.

Continued and excessive use invariably leads to intellectual and moral deterioration. Other drug habits play an insignificant rôle in the etiology of mental disease and mischief. In 1910 a commission appointed in Massachusetts to investigate the increase of criminals, mental defectives, epileptics and degenerates, states: "It is not possible to present reliable statistics on this point, but our investigations and the testimony

before the commissioner strongly emphasize the belief that there is an intimate relation between the abuse of alcohol and the amount of crime in society, and the number of epileptics and degenerates. Indeed, it is the belief of this commission, based on long personal observation, that the abuse of alcohol directly and indirectly, has done more to fill our prisons, insane hospitals, institutions for the feeble-minded, and almshouses, than all other causes combined."

The 1913 Report of the State Board of Insanity attributes alcohol as a causative factor of mental disease in 18.46% of all first admissions; and 11% of the cases first admitted to any hospital as some form of alcoholic insanity. Heredity appears as an etiological factor in 15.95% of the first admissions. At the Bridgewater Hospital during the same period, 20% of first admissions were diagnosed as some form of alcoholic insanity, and 40% of all others due in some measure to alcoholic intemperance. During the same period (1912-1913) out of a total of 4681 sentenced to the State Farm, 4136 were for drunkenness,—over 88%—and of the remaining crimes, it is safe to say that a majority, at least, were either directly or indirectly the result of intemperance. It has been estimated that 14.6% of the mental patients in the New York Hospitals are suffering from psychoses, the result to a greater or less degree, of alcoholism.

To what extent alcoholism in parents and grandparents is an etiological factor can only be surmised. Certain it is that far too frequently alcoholic excesses have existed in the ancestors, and that drunkards beget imbeciles, epileptics and criminals. Not only is it directly or indirectly an important etiological factor in the various forms of mental disease, but it is the direct and immediate cause of distinctive types of insanity known as the alcoholic psychoses, presenting certain characteristics more or less in common with numerous variations and manifestations, resembling to a greater or less degree the non-alcoholic insanities.

The causes of alcoholism may be sought not only in the social atmosphere, but also in the psycho-neurological make-up of the individual; environment and heredity underlie most drunkenness. It is perhaps impossible to say which is the more important. A craving for alcohol is not inherited, but the weak and unstable nervous system which renders the individual liable to excess in all things, renders him especially susceptible. Such an individual may be born into an alcoholic environment which favors the development of the habit in a soil previously prepared by his ancestors. Heredity manifests itself by demands for larger and larger doses, with impaired resistance to its action. It has been said that the drinker drinks because he is weak, and that he is weak because he drinks. As a result, he travels in a vicious circle, from which he has neither the ambition nor will power to extricate himself.

Overcrowding and bad housing produce in-

efficient people, and the saloons exist in proportion to the inefficiency of the community. The boy comes early in contact with those wise to the ways of the world. The saloon is the club-room of the neighborhood, whose members are easily admitted and to which there is no waiting list. Here, as in other walks of life, social drinking is the custom and the proper thing. The laboring man finds an ever ready welcome, a warm corner, and friends. He has no other place for social relaxation; presumably lacking education and training in self-control, he follows the drift of the current, and from the occasional social glass he becomes the steady drinker, and finally the drunkard, with the physical, intellectual and moral deterioration so characteristic. Such a boy or man does not deliberately make of himself an inebriate. An inebriate is not admired by him; rather he is looked upon with disgust. From the occasional drink, which may or may not be considered a vice, a habit is formed, which is satisfied only by increasing doses. Gradually and insidiously there is a breaking down of the moral character, powers of self-control and judgment, until a diseased condition is established, which may end here or finally terminate in a true psychosis.

The young, the ignorant, and weak-minded are not the only ones who succumb to this insidious poison. Its use exists in all classes, and the medical profession has furnished its share of wreckage. Disregarding the psychological questions involved, drinking is a social custom transmitted to us from a time unknown. The young man of the streets or the boy in college drinks because the crowd does. It adds to the pleasure of the moment, and is considered the mark of a man. Many go no further. Others lack sufficient strength of character, and with diminishing powers of resistance, assuming that the desire to abstain exists, go on to that point where they are unable to free themselves. Some have no desire to abstain and drink deliberately, either to forget their troubles or for the pleasure of the moment. It may be asked if such a state of mind is indicative of depravity or disease. If depravity, why? All drunkenness cannot be explained on a neurological basis, yet it is so intimately associated with a defective make-up that it is difficult to separate the purely vicious from the diseased.

The mental disturbances produced present every possible variation, from simple intoxication to profound dementia. The symptoms are frequently complicated by those of other mental diseases, rendering proper classification oftentimes difficult. Recognition is, however, of great importance, both to the individual and to the public. The alcoholic insanities are potentially dangerous, not only to the patients themselves, but to others, as they are frequently unrecognized or ignored until by some violent outbreak the peace of the community is disturbed.

Mental breakdown from alcohol is a gradual process, preceded by long and excessive drink-

ing, producing oftentimes an intangible deterioration before the definite onset of a true psychosis.

The psychoses especially dangerous are those characterized by active hallucinations and delusions. Cruel assaults and murder are a daily occurrence, and cause little comment, perhaps a word of pity for the wife or child, but no thought for their prevention. The majority of these attacks are probably the result of a drunken rage, while others are due primarily to an underlying mental disease, possibly complicated by a debauch, which is merely an incident in a pathological condition. It is impossible to consider all the manifestations of chronic alcoholism, consequently your attention is directed to a few of the more common types, exclusive of delirium tremens, seen in the hospital.

Acute alcoholic hallucinosis arising on a basis of chronic alcoholism is characterized by a sudden onset, with auditory, visual, tactile and olfactory illusions or hallucinations, accompanied by persecutory delusions and little clouding of consciousness. Recovery, with little or no intellectual damage, usually follows a first attack. Continued drinking, however, with further attacks, terminates as a rule in a chronic and permanent mental impairment, which remains more or less stationary when the patient is confined in an institution or otherwise deprived of alcohol.

Auditory hallucinations are most in evidence in this disease. The patient hears voices of friends, names, and mysterious telephone messages. He hears people talking over what is in his mind. He may hear the singing of angels or the voice of the devil; all very real, and no argument will convince him that he may by any possibility be mistaken. The voices are usually overheard and not addressed directly to the patient.

He thinks electric currents are applied, bad odors are detected, gases are pumped into the room at night, the food tastes suspiciously of poison or of some nauseous substance. Consciousness and orientation are usually clear. The patient appreciates his surroundings, and is able to see defects in others; general conduct is normal unless influenced by the delusions which are based on the hallucinations. The duration of the disease is variable. It may last for a few days or several weeks or months. Delirium tremens is closely allied, and must be differentiated, not only for the purpose of treatment, but also for legal reasons.

In delirium tremens, however, visual hallucinations predominate, all sorts of animals, reptiles and fantastic forms are seen moving about. Restlessness, tremor and fear accompany these frightful visions. The delusions are fugitive. Consciousness is clouded and there is disorientation: apprehension and attention are impaired and ideas are flighty. The duration is shorter and usually terminates by crisis. In well marked cases the diagnosis is not difficult, but, as in many other conditions, there are border line cases re-

quiring time for a diagnosis and proper classification.

There are two common types of chronic delusional states differing in mode of onset and clinical characteristics. In one there is usually a history of previous attacks of delirium tremens, or acute hallucinosis, in which there has been an apparent recovery, or the disease may represent the termination of an acute alcoholic hallucinosis. If preceded by an acute attack, the active hallucinations may have been in part corrected. The hallucinations of hearing develop again. The patients may complain that others are reading their thoughts, that voices are troubling them or electric currents are being applied. The delusions are fantastic and usually not elaborated, remaining the same from month to month. School knowledge, memory, orientation and consciousness are usually retained and the patients present a fairly normal appearance to the casual observer, although a thorough and careful examination will demonstrate a considerable degree of mental weakness. At first they may be irritable and impulsive, later becoming more pliable and humorous. They lack energy and initiative; as a rule the disease remains stationary under institution conditions, or when removed from alcohol. In time the delusions and hallucinations may subside, leaving the patient more or less demented and a burden for support by either the family or state. With continued drinking the disease is progressive and finally terminates in a deep dementia.

The other type, sometimes called alcoholic paranoia, is characterized by the gradual development of a paranoid condition in middle life in subjects who have been steady drinkers, without previous acute mental disturbance. They may or may not have been considered drunkards in the ordinary sense. In the beginning the diagnosis is difficult on account of the plausibility of the delusions which must be differentiated from the actual conditions and facts. They may state their troubles with emotion and with the appearance of truth. The disease is characterized by delusions of suspicion, persecution and jealousy, usually centering about the wife or husband. Aside from judgment defect, based on the delusions and general inefficiency of the drunkard, there may be little evidence of gross deterioration. Hallucinations are usually absent. Such patients misinterpret the most trivial acts as being evidence of marital infidelity. They may question the paternity of their children and accuse the wife of adultery. They may have delusions of poisoning. They neglect business and family. Although delusions regarding the mate are the rule, they develop erroneous ideas concerning others. They may attribute their trouble to jealousy or ill-feeling. The loss of a position, the result of their own incompetence and immorality, is considered the unfriendly act of the employer.

The subject of alcoholic paranoia may become

moody and revengeful, and if directly under the influence of alcohol, truly a menace.

The course of the disease is progressive, unless removed from alcohol, when the delusions remain more or less stationary and in time may subside. The return to the community and home is invariably followed by further drinking and a recurrence of the delusions. There are many such cases of moderate degree holding vague and visionary morbid ideas, going the rounds of the jails and work-houses. The majority are comparatively harmless, but they are of little economic value. The following cases, illustrative of the types seen in hospital practice, emphasize the fact that the drunkard is far too often suffering from an unrecognized disease rather than being merely a slave to a habit. Had these cases been recognized earlier, tragedies involving many might have been averted.

CASE 1. Male, age 47. Entered Bridgewater Hospital in March, 1913. Born in Ireland; came to America in 1882; common school education. No history of insanity in family. Father a hard drinker and sister and brother reported as intemperate. When a boy worked in a brewery with his father, who occasionally gave him beer, which he began to drink in moderation at 14 years of age. Claims to have refrained from drinking for two years after coming to this country. He worked in a cotton mill about a year and a half after landing. Since then has worked most of the time in clubs and hotels as waiter, bell-boy and kitchen helper. He has had many positions, many of which were lost on account of his habits. Has been arrested five times for drunkenness. He admits having hallucinations of hearing at three different times; the first in 1910 or 1911, when he heard voices speaking in a foreign language. He was unable to understand what was said, and thought that people were following him. While sitting by the Charles River he heard the voices, slashed his throat and jumped in, but the cold water brought him to his senses, when he swam about until rescued. He was treated at a general hospital. The voices disappeared in a few days. During the year 1912 drank to excess whiskey and beer. About two weeks before the commission of his crime, had been hearing foreign voices and thought people were after him. Christmas Day, 1912, while drinking with his sister and brother-in-law, words were passed which led up to the killing of his brother-in-law with a razor.

On admission to the hospital in March, 1913, the acute symptoms had largely cleared up. His attention was good and he told the history of his past life in detail. He said that his conscience did not trouble him and that he did not think God would make him suffer for the crime. "The reason is, Doctor, it was forced upon me, and I cannot remember anything about it. It seems that if God had intended me to suffer I would have had bad dreams and my conscience would trouble me." During the examination he was nervous and tremulous. There was a fine muscular tremor of the tongue, and twitching of the facial muscles. He realized that he had been sent to the hospital and that he had been insane. He no longer heard voices and he realized that they were hallucinations of hearing. However, he did not appreciate until later that a whistling sound in his ear at that time was also an

hallucination. On admission he had partial insight as to his condition, and realized that the trouble was caused by drink.

He had no recollection of the immediate details of the crime, although his memory was otherwise excellent. His memory concerning the details of the crime returned about six months later. At the present time he gives one the general impression of being damaged; is somewhat shaky and nervous, but presents no gross evidence of insanity. He is a good worker and takes rather more interest in current events than the average man in his station in life.

This is a case of chronic alcoholism or the disease 'inebriety' complicated by three attacks of acute alcoholic insanity. There are three periods during which he had hallucinations of hearing and delusions of persecutions based thereon. In one of these there is an attempted suicide, and in another a successful homicide. It is probable that under the routine of institutional life and removal from alcohol he will maintain a fair degree of mental health and that further deterioration will not take place.

CASE 2. Male, age 45. Sentenced to State Prison Feb. 25, 1905, for manslaughter. Committed to the Bridgewater Hospital April 17, 1905. The medical certificate states that when first admitted to the State Prison he was "dull and stupid," and later that he was "very depressed." He heard men talking about what he was thinking of; believed the other prisoners could hear him think; had headache and slept poorly, sometimes waking in the night covered with perspiration and his heart beating so that he could hardly breathe. Parents alcoholic, and he began to drink himself at 15 years of age. Arrested several times for drunkenness before present and last arrest. Admitted that he had been drinking to excess before committing the crime, but has little recollection of details. On admission to the hospital said: "I imagine that my thoughts are other people talking to me. They say things. I think, sometimes agreeable; other times not." Admitted having been troubled this way for about ten years, and also during a five-year period of abstinence; especially when he had any cause for worry. Attempted suicide several years before his crime. His memory was poor and he had little knowledge of current events. He was unable to tell when he was sent to State Prison. Felt badly over death of his wife, but did not greatly blame himself. For several years he had olfactory and auditory hallucinations, but at the present time, denies them. He now shows distinct signs of deterioration. His ideas and conversation are limited, attention is blunted, retention, insight and judgment poor. He is indifferent to his surroundings and to detention in the hospital. He is a good worker.

A case of chronic alcoholic insanity existing and unrecognized for ten years before the homicide. The fact that he was drinking at the time obscured the real condition, which was soon recognized by the prison officials. Under institutional routine and away from liquor he is likely to remain in his present condition indefinitely. If released he would, without doubt, return to his former habits and again become a source of danger.

CASE 3. Mill superintendent, age 62; born in England. Came to this country at twenty years of age. Admitted to the hospital January 19, 1912, charged with the crime, "Assault with a dangerous weapon." Father alcoholic. Patient began to drink at the age of 12, and has used liquor to excess for many years. Several times during his life suffered lapse of memory, discovering himself later in an adjacent town with no recollection of how he arrived there. He thinks that his present trouble followed testimony given by him in 1909, which he believes was displeasing to his employer, with whom he had been associated for twenty years, and that from this time his employer was unjustly prejudiced against him. Became suspicious; believed that he was being persecuted, and that his work was unjustly criticized. On account of his habits and inefficiency he lost his position in April, 1910; left shortly after for England, returning to this country in September. While in England and after his return he drank to excess and was treated for delirium tremens.

Between September, 1910, and March, 1911, he made several trips to the office of his employer for the purpose of obtaining a settlement. Claimed that \$50,000 was due him as a commission, in addition to his regular salary. He had no evidence to show that such was the case. On the contrary, his employer held his receipts for payments, covering twenty years. Patient claimed that he allowed this large sum to accumulate to his credit with no accounting, as he had absolute faith in his employer. In March, 1911, he purchased two revolvers in Boston, and carried them with him for the purpose of self-protection when he went to the offices of the mill to demand a settlement. During the controversy attempted to shoot his employer and one other. When arrested several unsigned checks for large amounts were found on him. He has persistently denied any recollection of the details of the assault, although his memory for events before and after is good. At the trial he was acquitted by reason of insanity, but through some technicality was released. A few days later he was re-arrested and committed to the hospital as a case of epileptic equivalent. He remained in the hospital over some two years, when he was taken out and brought to trial for the assault on the other party who was present in the office at the time of the attack. At this trial medical witnesses testified that he had recovered from the so-called epileptic equivalent, and no testimony was put in by the state to show that he was still insane. He was convicted, and sentenced to State Prison, in spite of this medical testimony and the fact that he had previously been acquitted by reason of insanity.

The essential points in the diagnosis are prolonged alcoholism, delusions of suspicion and persecution, the fear of bodily harm suggesting the purchase of two revolvers, indifference to his family and business affairs, a belief that a large sum of money was due him, and his superficial reason for allowing so large a sum to accumulate to his credit with no accounting. On admission to the hospital he talked pleasantly and intelligently on all subjects. He was correctly oriented, showed good judgment on general affairs, but poor judgment concerning affairs connected with his trouble. He had apparently maintained delusions concerning his former employer for two

years or more, and, without doubt, the delusions were aggravated by continued drinking. The debauch during which he committed the assault was merely an incident, but sufficient to classify him as a criminal rather than one suffering from mental disease. Thus far he has adapted himself to the routine of prison life and will probably continue as an orderly prisoner. It is possible that he will abstain when released, but a return to his former habits is to be expected.

The problem of drunkenness is far reaching, and its solution beset by tradition, social customs, business interests and indifference. It has too long been regarded from the policeman's point of view as an act punishable by arrest, fine and imprisonment.

It is unfair to classify all inebriates as criminals and to treat them accordingly; such methods are futile, illogical and tend only to arouse resentment and antagonism. Punitive measures have failed to diminish to any appreciable degree the plague of drunkenness. On the other hand, the medical profession has accomplished little from a curative point of view, and has little to offer, save a protest against such methods, the general attitude of mind regarding the inebriate, and the source of his production, social drinking. The inebriate, who under the influence of alcohol commits crime, places himself as a rule in the criminal class, unless there is an obvious degree of mental defect. Such defect may consist of a definite psychosis and go through the court unrecognized if it is shown that he was drunk at the time of committing a crime, but not shown that the debauch was simply an incident in a chronic disease of the nervous system. The law judges of responsibility from one point, whereas the physician, in contact with life from another angle, may have an entirely different view. Yet, within the medical profession through an honest difference of opinion, or lack of knowledge and a full appreciation of the significance of the signs and symptoms of the disease, the drinker, charged with crime or drunkenness, does not always receive the consideration which is his due. Society having made the drunkard, has no moral right to punish him, although it may confine him for therapeutic purposes or remove him as a menace from the community. It is obvious that for some institutional care is the only remedy. How long such custody should be maintained must be determined in each individual case, and even then we shall be disappointed with the results. Hope for the cure of the drunkard is remote unless there is a sincere desire on his part to be cured. It is useless to expect the poisoned alcoholic to act as a normal individual. We know that various changes occur in the viscera, blood vessels and brain, and that the degree of destruction varies in the individual and with the quantity taken. Possibly the damage is purely functional, but even then it is no less disastrous so far as results are concerned. The promises, remorse and apparent sincerity of one recovering from a debauch, will

deceive even those who have had the most experience. All sorts of excuses are made except the real one, which is the diseased nervous system and its unrecognized demand for alcohol.

The drunkard even deceives himself, but that his declarations and promises for the future are merely empty phrases is only proved by his subsequent conduct. He may go forth confident in his strength, but with a lurking desire or subconscious intention for a drink, which he feels so sure of handling, but which is surely his undoing. Whether or not the inebriates now living are cured is of little importance compared with the saving of future generations. Of those who early in life begin the moderate use of alcohol, none can foresee the degree of degradation which may follow. The habit is usually established at a time when youth is easily led, when it is considered more or less necessary to do as the others do, or perhaps go one better. It is during this period that one may have hopes for the future, for up to the present time the results of all known methods of treating inebriety are unsatisfactory and discouraging. We cannot say an individual has been cured unless he stays cured. An occasional cure does not prove any method. If prevention is the remedy, how shall we reach the boy in college or the young man in the shop? Can he be reached under existing social conditions, which license the manufacture and sale of intoxicating liquor? Abstinence has not, and will not exist when liquor is obtainable, and yet it is the only sure means known for the prevention of drunkenness.

Russia has autocratically pointed the way to national prohibition, and the recently enacted narcotic law of this country is a step in the same direction. If prohibition is expedient in a country at war, would not the efficiency of a country at peace be correspondingly increased? Although prohibition has not been an unqualified success, it has, however, diminished the amount of drinking in the so-called dry territory, and if enforced as vigorously as the Government pursues Kentucky moonshine, drunkenness would necessarily be checked. Public sentiment is wakening, and will in time be in a receptive mood for more active or radical temperance reform. If drunkenness is a disease, and prevention the remedy, it is a problem in preventive medicine and as such should receive the serious thought of the whole medical profession. The responsibility for the health of the people, and incidentally their prosperity, is ours, and thus far we have failed in performing our full duty in meeting it. It is not a question of reform from a sentimental, moral or religious standpoint, but a public health measure which we have looked upon with apathy and indifference. Temperance reform of the past has made little progress, for the reason that it has approached the subject from the wrong quarter. People do not like to be told what they should or should not do because of the expense or because someone be-

lieves a certain act to be a sin. They prefer to decide such matters for themselves. We should disregard the question of whether it is right or wrong, and present the subject as a health measure as vigorously as we have pursued the tubercle bacillus and escaping sewer gas. People should be taught by precept and example that moderate drinking undermines mental vigor and bodily strength; that chronic alcoholism is a disease and that a certain number of moderate drinkers will surely succumb.

THE CEREBROSPINAL FLUID IN DIAGNOSIS AND IN TREATMENT.*

BY W. H. WATTERS, M.D., BOSTON.

IN preparing a paper upon the subject of the cerebrospinal fluid it has been the aim of the writer to give a general idea of the present status of our knowledge of the cerebrospinal fluid such as might appeal to the general practitioner rather than to present the more technical side in an attempt to interest the specialist alone.

That fluid of some kind existed in the cavities of the brain has probably been known since the time of Galen. Concerning its functions there has been a great amount of speculation. By some it has been considered to be the home of the animal spirits. By others it was thought to be a sort of a lubricant. For centuries, however, practically nothing was known about it and in fact even at the present day a great deal of our supposed knowledge is rather nebulous.

The first serious attempt to remove cerebrospinal fluid was probably made by a Dr. Corning, an American who in 1885 performed ventricular puncture and in 1889 made a lumbar puncture preceded by a laminectomy.

From the standpoint of actual investigation and extensive study Quinke may be justly called the originator of lumbar puncture as now widely performed. He in 1891 published an epochal paper upon the subject and by so doing opened up an entirely new field for investigation. So complete was his study that the technic employed by him is still followed by almost all workers.

Technic. It will certainly be unnecessary in this place to give in detail the method of performing lumbar puncture. Probably most of you have done it many times. In my personal experience, it has been found advantageous to use some local anesthetic, usually ethyl chloride, to deaden the pain of skin puncture. Occasionally in hyperesthetic individuals and in children

light ether or chloroform anesthesia is advantageous. A gold needle similar to those used for alcohol trigeminal injections has proven very satisfactory as it lasts longer than the ordinary ones, where rusting rather rapidly occurs. My former routine of lateral puncture has now been replaced by the median one. The latter is usually less difficult and less painful, particularly in intraspinal injections.

The reasons for doing lumbar puncture are varied, but almost all depend upon the attempt to clear up an otherwise uncertain diagnosis, or as a preliminary to the intraspinal introduction of some remedial substance. At times it is performed for therapeutic reasons in cases where increased intracranial pressure is suspected and its temporary relief is thought to be desirable. The principal contra-indication is posterior cerebral, or particularly cerebellar, tumor. Here the procedure must be most carefully followed and only a very small amount of fluid withdrawn.

Physiology. It may be well in passing to say a few words about the physiology of the cerebrospinal fluid. Until very recently much uncertainty has existed concerning the origin of the fluid, some authorities claiming it to be merely a transudate, while others considered it to be a true secretion. Probably the most satisfactory studies in this connection are reported in the September, 1914, number of the *Journal of Medical Research* by Cushing and Weed. It can now be quite definitely stated that the fluid is secreted by the choroid plexus, part going to the lateral ventricles and part to the subarachnoid space. Some may also come from the perivascular system. After secretion there is probably a more or less definite circulation toward the point of exit, which seems to be the arachnoidal villi projecting into the dura, particularly near the sinuses and the dural vessels. The rapidity of the secretion apparently varies under different conditions of pressure. When the pressure is released by lumbar puncture and fluid is removed, it has been demonstrated to have been rapidly replaced in a very short time.

Physical Properties. Under normal conditions the fluid is perfectly clear, has a specific gravity of 1003-1010, and is slightly alkaline. Occasionally it is more or less pinkish in color, due to penetration by the aspirating needle of some small blood vessel. Such blood has no significance. Under certain pathologic conditions blood may actually be present in the fluid, either fresh, pinkish red, or altered, brownish red. Among causes for such may be mentioned intraventricular hemorrhage, hemorrhagic pachymeningitis, and various forms of local injury to the spinal cord from external violence.

Pressure. While divergent opinions exist concerning the value of pressure determination at the time of lumbar puncture, it seems wise to ascertain it always. This procedure is particularly desirable in watching for the danger signal in removing fluid prior to intraspinal

* Read at the February meeting of the Norfolk District Branch of The Massachusetts Medical Society. The work covered is based on studies made, largely, at the Evans' Department of Clinical Research and in the laboratories of Boston University.

injections and in ascertaining the amount of serum that can be safely introduced. In my personal experience, uniformly placing the patient on the side, in bed, and always using a water manometer, the average pressure is found to vary from 50 to 80 m.m. In pathological states it ranges from 30 to 300 m.m., or even higher. Meningitis and brain tumor are particularly liable to be accompanied by high pressure. Many cases of tabes also show this increase, while some do not. From personal observation the earlier and more active cases seem to have this higher pressure, while the more advanced or latent cases may be more nearly normal. Incidentally the former have manifested a more satisfactory degree of improvement after intraspinal salvarsanized serum than have the latter.

Examination of the cerebrospinal fluid can be divided into three sub-divisions, chemical, microscopical and serological.

Chemical. From the standpoint of diagnosis, determination of the presence and amount of protein is the most important procedure. This substance is present in the normal fluid in such minute amounts as to be unrecognized by the usual clinical tests, but is found by them when present in increased amount. Several such tests are now commonly used. That introduced by Nonne and Apelt consists of the mixture of equal parts of the spinal fluid and neutral saturated solution of ammonium sulphate. An opalescence or turbidity occurring within three minutes is said to indicate a globulin excess. The Ross-Jones method also uses ammonium sulphate, but by superposition as a ring test instead of a diffuse mixture. A popular method in this country has been devised by Noguchi. In this a 10% solution of butyric acid in saline is used as the indicator (add .5 c.c. butyric acid solution to .1 c.c. fluid, boil, add 1 c.c. normal sodium hydroxide and boil). Globulin in increased amount is indicated by a flocculent or granular precipitate. The most satisfactory test in my laboratory is that introduced by Lange, as it gives not only qualitative but quantitative results. It depends for its efficiency upon a solution of gold chloride prepared in a very careful manner, the various steps of which will not here be described. Various other tests have been devised, but are probably less satisfactory.

The clinical significance of protein products in the cerebrospinal fluid is not such as to enable one to make a diagnosis from it alone. As a symptom or indication, added to others of a clinical nature, it is often decidedly valuable. In acute exudations with inflammation of the meninges, in hydrocephalus and in various forms of cerebrospinal syphilis, including tabes and paresis, globulin is usually increased. Its absence is often of greater significance in certain cases than is its presence in others. To illustrate: a case of tabes with globulin in excess comes for intraspinal or intravenous salvarsan treatment. Here a positive Wassermann may frequently be

changed into a negative one, but often without appreciable effect upon the globulin content. Under these conditions the prognosis is much less favorable than in others where the amount of globulin shows progressive decrease. In other words, the Wassermann reaction is at times more readily influenced than is the globulin, and unless the latter shows a corresponding degree of improvement the future outlook is less hopeful.

Apart from globulin, the spinal fluid is examined chemically for sugar, acetone and diacetic acid in diabetes, but such tests offer little from the diagnostic standpoint. Arsenic has at times been demonstrated in the fluid for a number of days subsequent to intravenous injection of salvarsan and neosalvarsan. Urotropin has also probably been demonstrated.

Microscopic Examination. This gives much more important results than does the chemical examination. Here attention is first directed to the cell count, then to the varieties of cells, and finally to any bacteria that may be present. The cell count should be made as soon as possible after the fluid is withdrawn. The technic is similar to a reversed leucocyte count, as far as preparing the specimen is concerned. A "white" pipette is filled to the mark .5 with a staining fluid and then to the mark 11 with the fresh, thoroughly mixed cerebrospinal fluid. The ordinary Turck counter is then used, or better the Fuchs-Rosenthal modification. The cells, stained lightly, are then readily counted, and at the same time the varieties can be determined. The normal cell count varies between 2 and 10, probably averaging 5 to 8. For obvious reasons, if there is admixture of blood due to penetration of a vessel at the time of puncture the disks must not be counted. In fact, from the standpoint of cytology, blood disks are practically eliminated. Departing from normal, the cell count may go to fifty, one hundred or more in tabes or tuberculous meningitis, to thousands in some of the acute infectious forms of meningeal inflammation. A count, then, of more than ten cells per cubic millimeter may usually be regarded as a departure from normal and an indication that some cause for such a departure be sought for. Of first importance in such a search is the estimation of the several varieties of cells present. In the normal fluid the cells found are of the lymphocyte variety, either large or small, but under pathological conditions other varieties appear. Thus a lymphocytosis may suggest, as will later be seen, a tuberculous meningitis, a tabetic lesion, a brain tumor, etc. On the other hand, a polynucleosis is equally able to make one consider the presence of some acute inflammatory disturbance. Differentiation between the small and the large lymphocytes is of no diagnostic significance as far as our present knowledge goes. After much prolonged research, various workers have devised and described very elaborate classifications of the different cells sometimes found, but I can see no practical ad-

vantage over the simple differentiation above described.

As will be noted later, one of the most important features of cerebrospinal cytology is the progressive changes that are observed as various forms of treatment are instituted to remedy or cure the pathological condition present. Here we often have a prognostic element as well as a diagnostic one.

Having now made the cell count, both qualitative and quantitative, our attention is next directed to the possible bacterial content. It must be noted that while the bacteriological examination is here mentioned rather late in the course of the work, its actual performance must be the very first procedure, and one begun very promptly lest outside contamination occur. Emphasis is again placed upon the need of absolute sterility of all instruments, utensils and containers. Frequently an entirely adequate diagnosis can be made by taking the microscope and a little stain to the bedside. By this means the presence of the intra-cellular meningococcus can often be demonstrated and many valuable hours saved by immediately instituting the proper treatment. The pneumococcus is also often found with its characteristic halo, as may be the streptococcus, the staphylococcus, the influenza bacillus, etc. It is always well to make cultures upon various culture media in order to allow for further more detailed study. Detection of the bacillus tuberculosis presents a much more complicated problem. When the cell count is normal the search for the bacilli is usually less thorough and painstaking than when a pleocytosis is present, as the former somewhat contra-indicates tuberculosis, while the latter may strongly suggest it. Microscopic examination of such a suspected case consists of study of a carefully centrifugated and stained sediment. Sometimes the bacilli may be enmeshed by adding a few fibres of absorbent cotton to the centrifuge tube. Always few in number, a prolonged search is almost invariably necessary. It must be remembered that a vain search by no means excludes the possibility of the presence of the disease, but that guinea-pig inoculation and tuberculin test of the patient are then in order.

Cerebrospinal Serology. This subject at once opens up a topic to which there can scarcely be placed any limit, namely, the Wassermann reaction. I can imagine the looks and feelings of disapproval among this audience did I here take the opportunity of launching out upon a dissertation of the Wassermann reaction. Suffice it to say that I will spare you such an imposition. As this is one of the most important of the more recent tests and is often of vital importance in neurological investigation it cannot be passed without some notice however. In the first place the Wassermann reaction cannot be regarded as an absolutely specific test, because the antigen employed may have nothing whatever to do with syphilis or its products. A normal beef heart, a human heart or a guinea-pig heart seems to be

equally as efficient as a source of antigen as does the congenital fetal liver. Some of the more delicate antigens, particularly those to which cholesterolin have been added, have in my hands proven even too delicate to be fully relied upon in diagnosis, but have been of much value in determining the time when it is safe to desist from treatment of the known positive case. In other words, the cholesterolin antigen is less reliable than the others in positive cases, but more dependable in negative ones. It is my custom, therefore, always to run through duplicate tests with both antigens prior to giving definite reports. By so doing it is believed that we make but comparatively few errors in the test. Errors there must be in any extensive series of cases, and it is at times a question on which side one may err. At such times the patient is always given the benefit of the doubt in the diagnosis of the disease, when it is a question of discontinuing treatment. The clinician who depends absolutely upon a single positive Wassermann without other corroborative symptoms or history is the victim of an unduly or unwisely enthusiastic pathologist, and will at times bitterly regret it. It is far from my intention to belittle the test, but nothing can do more harm than to give to it undue credence where not justified. Of course the more often a positive result is obtained in such cases the greater the probability of the presence of the disease.

The elaborate measures necessary in performing the test cannot be here considered, nor will any time be now devoted to its occurrence and significance in the blood serum. The older Wassermann system, with sheep's corpuscles and antishcep amboceptor is the one of choice in the laboratory at Boston University after considerable experimentation with others, particularly Noguchi's. Spinal fluid to be tested should be not more than two or three days old, and even during that time it should be kept cold and sterile. My custom is to place the major dependence upon the test where the amount of fluid used is twice the amount of blood serum used for the same system. A greater percentage of positives can be obtained by using increasingly larger amounts of fluid, but with, I believe, less dependable results.

Having thus briefly considered the various contents and attributes of the spinal fluid, it may be well to turn our attention to and study equally briefly those diseases in whose recognition examination of this fluid plays a part.

Epidemic Cerebrospinal Meningitis. This disease is now known to be caused by the meningococcus, or as it was earlier called, the diplococcus intracellularis meningitidis. It is characterized by an acute purulent exudation into the sub-arachnoid space and by considerably increased pressure. The cerebrospinal fluid appears as a turbid, at times almost milky, substance. Upon chemical examination it contains, as might be expected, a greatly increased amount of globulin, while the microscope shows a very high cell

count. These cells, the very great majority of which are polynuclears, contain a varying number of the biscuit-shaped diplococci that so closely simulate gonococci in appearance. Diagnosis in such a case is very easy. It is particularly interesting to note the progressive decrease in the cell count and the diminution in the number of bacteria that in favorable cases follows the administration of the specific treatment.

Acute Suppurative Meningitis. This form of the disease differs from the preceding principally by being caused by non-specific bacteria and by not being benefited by the specific treatment, antitoxin. In my experience the streptococcus has been the most frequent invader, with the pneumococcus a close second. Staphylococcus has been encountered less frequently. Typhoid bacilli, gonococci, diphtheria bacilli, I have not yet found. They are, however, occasionally present. Here, as in the meningococcus type, the fluid pressure is increased, the globulin is in excess, the cell count is high and the causative bacteria are found both by direct microscopic examination and by culture. In certain cases under personal observation, it has been most gratifying to note the rapid, even though temporary subsidence of symptoms following lumbar puncture and removal of a considerable amount of fluid. The removal of the excessive pressure has been followed by a rapid cessation of the pain and amelioration of the allied symptoms. A gradual return of the unfavorable condition due to gradual re-accumulation of fluid has been repeatedly successfully relieved by further punctures. By many repetitions of this method I have seen cases entirely recover that seemed to be otherwise entirely hopeless. When it is remembered that by so doing fresh supplies of fluid are secreted, bringing to the battleground new recruits in the form of increased amounts of antibodies from the blood, the logical reason for such a procedure may be understood. These antibodies are at best not abundant and it may not be impossible to hope for some new method of attacking the disease in the not distant future.

Tuberculous Meningitis. Different from the other varieties of meningitis, the fluid in the tuberculous form is clear, or at most but slightly opalescent, globulin as a rule is increased, and pleocytosis is usually found, but occasionally a normal cell count is encountered. The increased number of cells is composed largely of lymphocytes. When such an increased lymphocytosis is discovered in a child or young adult with symptoms of meningeal irritation the presence of tuberculous is always suspected, entirely irrespective of the ability to demonstrate tubercle bacilli. The increased permeability of the meninges to nitrates in tuberculous meningitis may be of some value as a diagnostic factor, but of this I can say nothing from personal experience.

Cerebral Hemorrhage and Cerebral Thrombosis may or may not be of syphilitic origin. The Wassermann reaction will differentiate the two

conditions, once the anatomical diagnosis is made, but is of no assistance in gaining that diagnosis. Blood may or may not be present in the spinal fluid in hemorrhage, dependent upon whether the bleeding occurs near the ventricles or the subarachnoid space. In cases of suspected brain tumor, lumbar puncture should be performed with unusual care for fear of unduly disturbing the already altered intracranial pressure equilibrium. But small amounts of fluid should be withdrawn, and often less reaction ensues if the pressure is maintained by injecting an equal amount of saline. Pressure in these cases is very often increased, and at times pleocytosis is present. It is stated that in hydrocephalus beneficial clinical results can follow repeated punctures, reducing thereby the high pressure. Anterior poliomyelitis has been extensively studied in recent years, and an article by Peabody, Draper and Dochez of the Rockefeller Institute gives much information concerning the spinal fluid. They determined the presence of pleocytosis with low globulin content very early in the disease, this gradually changing to a low or normal cell count, with increasing globulin as the symptoms became more pronounced. The virus, when experimentally introduced into the blood, passes to the fluid in from three to five days, probably by way of the choroid plexus. The fluid in epilepsy shows nothing of definite diagnostic value.

Syphilis. That condition, for the detection and treatment of which by far the greatest number of lumbar punctures are now being performed, is syphilitic involvement of the nervous system. Now that tabes dorsalis or locomotor ataxia and general paresis have been proven to be definitely due to the treponema pallidum, these two diseases can be associated with cerebrospinal syphilis, and all three studied together.

Without any doubt the central nervous system often shares with the rest of the body in receiving numbers of the treponema at that time, midway between the primary and secondary stages, when there is a general diffusion of the infectious agents throughout the body. Cases have come to the attention of most of us, of the appearance of a clearly defined cerebrospinal syphilis from five to eight months after the initial lesion.* Incidentally it may here be noted that the increasing tendency of many physicians of refusing to dismiss as cured any case of syphilis without first demonstrating a perfectly normal spinal fluid is most commendable and deserves more general acceptance. Kaplan well suggests the idea that "the treponema pallidum permeates the entire system of a patient in the beginning of the disease, gradually settling in various tissues, which will later determine the type of luetic infection, as e.g. visceral, vascular, cutaneous, nervous, etc." If this is true the syphilologist

* Wile and Stokes estimate that about 60 per cent. of all secondary cases show some involvement of the central nervous system. They state that as a possible guide to prognosis and as an aid to diagnosis spinal puncture in cases of secondary syphilis can scarcely be overestimated.

gist can foretell with some precision those patients who, if left alone, will be liable to develop late cerebral manifestations. In other words, careful examination of the spinal fluid should be made in every case of syphilis treated in the primary or secondary stages, prior to discharging the patient as cured. This, of course, is in addition to repeated Wassermann tests of the blood. If such a procedure is instituted, and when evidence of the disease is there found, proper therapeutic measures are taken to remove it, the incidence of cerebrospinal syphilis, tabes and paresis will be very greatly diminished. We have another illustration of the old saying, "an ounce of prevention is worth a pound of cure." In this early stage the organisms are comparatively accessible and are much more amenable to treatment than when they later become deeply buried in relatively avascular tissues. The question now naturally arises, what are the serological indications of early syphilitic involvement of the central nervous system or of impending appearance of symptoms? In response it may be stated that a positive fluid Wassermann, a globulin excess, or a pleocytosis, either combined or singly should, when accompanied by a positive serum Wassermann or a luetic history, always render one suspicious of cranial involvement, even in absence of symptoms. When with these one finds the Argyll-Robertson pupil, a tardy or uncertain foot, unsteady station, an absent knee jerk, some speech disturbance, an uncertain memory, or any one of several other single symptoms, the indication for energetic treatment becomes still stronger. It is gratifying to note the prompt response in serology that usually follows the institution of such treatment. The cell count falls steadily from 100 to near normal limits, the globulin excess subsides and the intensity of the Wassermann progressively decreases and hopefully entirely disappears. Later serological tests should be made after lumbar puncture in order adequately to watch the progress of the patient. In such a case the subsequent appearance of tabes or paresis would seem to be highly improbable. Not only should the above procedure be followed in every case of syphilis that may be encountered in future, but it should be equally applicable to those cases that have been treated in the recent past and are now apparently cured. In such cases lumbar puncture would without doubt show some with distinctly positive serology, cases that are in all probability prospective subjects for future neurological trouble. I am aware that some will consider these opinions to be those of an enthusiast and not suitable for practical application. Doubtless they may never be universally applied, as for various reasons all syphilitic patients cannot be subject to such tests, yet I fully believe that the facts already gained by spinal fluid examinations and clinical experience, entirely bear them out. In a comparative sense it is easy to bring our remedial agents into contact with the syphilitic organisms when they are on

or within the meninges, freely accessible to the blood stream. Vastly more difficult or impossible is it to reach them, when after months or years they are found deep in the tissues with very poor blood supply. If serologic tests indicate the need of efficient therapy in early syphilitic meningeal irritation they equally well indicate it in the more pronounced clinical manifestations of the disease. These manifestations are varied, dependent upon the location of the infectious focus, and are all grouped under the general head of cerebrospinal syphilis. In the spinal fluid the constituents vary considerably, dependent upon the areas involved. The most constant abnormality noted is the excessive pleocytosis. The cell count is the highest found among all the syphilitic nervous diseases, it being seldom below 100 and often as high as 1000, or even more. Such a count, consisting as it does mostly of lymphocytes, is an indication of active meningeal irritation. Globulin is present in excess in the larger percentage of cases, while the fluid Wassermann may or may not be positive. The serum Wassermann is usually positive. Here again the great value of cerebrospinal fluid examination is found, not merely in assisting in diagnosis but in ascertaining the efficiency of the therapy employed and the period of time over which it should continue. I assume throughout this entire paper that it is now taken for granted that observation of clinical symptoms is never a sufficient indication of the efficiency of the treatment or the time when it may with safety be discontinued. Did time permit cases might be cited admirably illustrating this point. Up to this period, therefore, that of cerebrospinal syphilis is the time par excellence for a favorable prognosis under efficient therapy.

If we grant the assumption of some neurologists that the treponema now pass from the meninges to the cerebral tissue and then bury themselves deeply into that tissue, as indeed we know they do, we pass from the realm of the favorable to that of the unfavorable, from the hopeful to the unfavorable prognosis, from cerebrospinal syphilis to paresis. As we make this transition our cerebrospinal fluid also shows changes. As the meningeal irritation has largely subsided the high cell count is replaced by a low one; this is the most important alteration. Globulin continues to be found in excess, and both the serum and the fluid Wassermann are positive in a greater percentage of cases. In fact the serum Wassermann is practically always positive until a very late stage of the disease, when it occasionally disappears. The gold chloride test is supposed to be of particular value here, but not sufficient data have been accumulated to speak of it with certainty. Whatever treatment is instituted should be carefully followed by serologic study, the aim being particularly to render the strong positive Wassermann less active or negative. How much can be done by some of the later methods is still problematic.

It is safe to say, however, that the great desideratum is early diagnosis, in order to attack the organisms before they are fully entrenched.

Tabes Dorsalis. In this disease the fluid findings are notably variable, and as such seldom render possible a definite diagnosis apart from the clinical symptoms. The Wassermann reaction is probably as often negative as it is positive, although the serum Wassermann is usually positive. Globulin may or may not be present in excess. The most frequent and important departure from normal consists in an increased cell count. This varies from 15 to 100, seldom going higher. The cause of the varied findings is probably found in the stage of the disease manifested by the patient at the time of the puncture and in the activity of the infection.

Assuming this to be correct, then fluid examination becomes of much importance as a means of ascertaining the stage of the disease and of giving a prognosis. It also offers a very valuable guide to the advisability of instituting active treatment. It seems safe to say that a fluid showing pleocytosis, globulin excess and a positive Wassermann is indicative of more hope from active treatment than is one where the findings are practically all normal. The reason is that the former is a more recent or more active infection, while the latter represents a comparatively pure degenerative process. Did time and scope of this paper permit, a discussion of the more recent forms of therapy in tabes might be of much interest, particularly the salvarsanized serum, mercuialized serum, etc. Such is at present inappropriate. Selection of suitable patients for such can only be made by serologic as well as by clinical study, and it is impossible adequately to follow up the results of such without further laboratory studies of the aspirated fluid. Allow me to illustrate. A case of tabes comes to the hospital. In his serology there is but little or no departure from normal. He will usually show posterior spinal sclerosis and an inactive stage of the disease. He is sent home with an unfavorable prognosis, possibly after one salvarsan injection for provocative purposes. It is not fair to expect any treatment to replace tissue actually destroyed and functionless. Another case comes with a cell count of 75, a globulin in excess, a positive Wassermann in both fluid and serum. Here we believe there exists more or less active process in the meninges and offer to the patient more or less hope from treatment. This hope must lie, not in replacing already destroyed tissues, but in arresting the progress of destruction and in allowing the subsidence of the meningeal exudative processes. It is thus often possible to remove the lightning pains, to bring back to normal the areas of hyperesthesia, to eliminate the girdle pains, and to remove many of the symptoms of the disease, even including some cases of ataxia. If, during this treatment, the most efficient form of which is the intraspinal salvarsanized serum, the serology shows progressive improvement, including a

negative Wassermann, a favorable prognosis seems justified. If, on the contrary, the Wassermann continues positive, or becomes even more strongly so, possibility of a tabo-paresis should be considered with a resultant unfavorable future.

CONCLUSIONS.

In concluding this paper certain things may be briefly summarized as follows:—

Lumbar puncture is a relatively simple and safe procedure when properly performed. Examination of the fluid removed should include chemical, microscopical and serological tests. By examination of the fluid it is possible usually to recognize with certainty and to differentiate the various forms of infectious meningitis. Repeated lumbar puncture is not infrequently of definite therapeutic value in such cases. The cerebrospinal fluid should be carefully studied prior to discharging as cured any case of syphilis, irrespective of the stage in which it has been treated. Examination of the fluid is an essential in properly following the treatment of cases of syphilitic involvement of the nervous system.

Clinical Department.

RESULTS OF THE TREATMENT OF PYORRHEA ALVEOLARIS AND ALLIED CONDITIONS WITH EMETINE HYDROCHLORIDE AT THE DANVERS STATE HOSPITAL—PRELIMINARY REPORT.*

By H. I. GOSLINE M.D.,

Assistant Physician, Danvers State Hospital.

This report is the culmination of treatment first started at the Danvers State Hospital in November, 1914, and pursued perhaps more systematically during February and March, 1915. There were 42 cases, grouped for convenience of description under the headings: spongy gums, 14; very spongy gums, 12; spongy gums and loose teeth, 16.

The treatment was the so-called full treatment and the local treatment. The full treatment consisted in the administration of emetine hydrochloride gr. 1-6 twice a day subcutaneously, and the application of the wine of ipecac to the gums twice a day for one week, followed by a second week's treatment in which the gums were swabbed with wine of ipecac and an injection of emetine hydrochloride in 1-3 gr. dose was administered once a day.

* Danvers State Hospital Contribution, No. 55. Read at the meeting of the New England Society of Psychiatry at Northampton State Hospital, March 30, 1915.

The results were grouped as showing marked improvement, moderate improvement, or slight improvement. The 14 cases with spongy gums were all treated locally. Eleven showed marked improvement, two moderate improvement, one slight improvement. (The last had great masses of tartar about the teeth, making thorough application impossible.)

Of the 12 cases with very spongy gums, eight were given full treatment, and four local treatment. Seven showed marked improvement, two moderate improvement, three slight improvement. Of the four cases with very spongy gums treated locally, two showed moderate improvement, and two showed slight improvement. Only one of the eight cases receiving full treatment failed to show well marked improvement. No obvious reason for this was discovered.

Sixteen cases with spongy gums and loose teeth, regarded clinically as true Riggs' disease, or pyorrhea alveolaris, were treated; 14 by the "full" method, two locally. Twelve showed marked improvement, four moderate improvement. Of the two treated locally in this group, one showed moderate improvement and one marked improvement. (The case which showed marked improvement had gums which were only slightly swollen to start with, and it is possible that here loose teeth were due to some other cause.) Three cases which received full treatment and showed only moderate improvement had especially marked sponginess of the gums plus loose teeth, the gums bleeding easily, and it being possible in one case to express pus from a small sinus over the root of the right upper canine.

I have used the terms "marked improvement," etc., because I wished to reserve the term "cure" for those cases in which the ameba had been demonstrated before treatment, had disappeared during treatment, and beside which "controls" had been run. Cure should express something more scientifically exact than was possible in this series.

By marked improvement I have designated those cases in which a return to the apparently normal hue and resiliency of the gums was evident. Moderate improvement has meant that there is still left some sponginess, or possibly a slight redness or readiness to bleed, but that improvement is apparent. Slight improvement is more of an impressionistic term and means that there has been little, if any, improvement.

Our results in a certain sense show controls in that, of the 12 cases of very spongy gums, those treated locally showed only moderate or slight improvement, while those treated with emetine in addition to the local treatment showed 87.5% (7/8) marked improvement. The group with loose teeth and spongy gums showed 78.6% (11/14) marked improvement, but in no case with loose teeth did the teeth become firmly set once more.

We are now engaged in examining the teeth of a large number of cases that appear clinically

as pyorrhea. In several cases the ameba has been demonstrated already. It is our aim to demonstrate the ameba or some of the other organisms claimed to be the cause of pyorrhea, and with this material at hand we may later be able to use the word "cure" in the scientifically exact sense.

Medical Progress.

REPORT OF PROGRESS IN PEDIATRICS.

A RÉSUMÉ OF THE RECENT LITERATURE OF DISEASES OF THE GENITO-URINARY TRACT IN CHILDREN.

By RICHARD M. SMITH, M.D., BOSTON,

AND

RICHARD S. EUSTIS, M.D., BOSTON.

URINE IN INFANCY.

ENGEL¹ contrived an ingenious apparatus to determine the frequency of micturition in infancy and the amount voided at one time. It consists of a small vessel of 10 c.c. capacity in which are two platinum electrodes. As soon as the infant voids, the urine completes the electric circuit and rings a bell which summons the nurse. Any excess of urine overflows into a larger vessel below. He found that the average infant receiving about 800 c.c. of fluid a day voided 20 to 30 times a day, 10 to 20 c.c. at a time, and passed about 500 c.c. in twenty-four hours. The frequency of micturition diminished when the infant was asleep and increased when it was awake and restless. When the fluid intake is increased up to 1600 c.c. a day, the infant voids 60 to 70 times in twenty-four hours. The maximum amount passed at any one time during the first year is 60 c.c.

It is generally recognized that albuminuria in the newborn is of common occurrence. Heller² has been able to detect it at least once in each one of 31 normal infants. Franz and von Reuss³ also found it very common. In addition to the ordinary albumin there occurs a second substance known as the "acetic acid body," which causes a slight cloud on the addition of acetic acid to the urine in the cold. The most probable explanation for this is that the acetic acid sets free from their salts certain albumin precipitating substances (chondroitin-sulphuric acid, nucleic acid, bile acids, etc.), which then form insoluble compounds with the serum albumin already present in the urine. These albumin precipitating substances are apparently present in increased amounts during the first few days of life as well as in orthostatic albuminuria in older children. Thus this cloud on the addition of acetic acid is not only a measure

of the serum-albumin present, but also of the albumin precipitating substance. If there is an excess of the latter the addition of an albumin solution to the filtrate will bring down a further precipitate. Franz and von Reuss³ conclude that "the low grade albuminuria, as well as the excretion of albumin precipitating substances, discovered almost without exception, both of which the newborn show especially during the first three days, is a result of the act of labor; that is, of the change in the circulation which takes place in all cases during delivery. We have to do with a wholly physiological symptom which, to be sure, may be influenced by many accidental factors of physiological and pathological nature."

The frequency of albuminuria during the first few days of life is shown by the following table from Franz and von Reuss³:—

They also tested for sugar in the urine of many of the infants, having in mind Hoeniger's statement that a true glycosuria occurs after forceps deliveries. In none did they find a surely positive reaction with Nylander's reagent, and the urine of the spontaneously born children was always sugar-free.

Differences in the urine of breast and of bottle fed infants have been studied by Ostrowski.⁴ Fifteen or 20 drops of a 2% silver nitrate solution are added to 5 c.c. of the urine. A white precipitate forms which, if the urine is from a breast fed infant, turns black after standing ten

minutes, or immediately on boiling. If the infant has been fed on the bottle the precipitate remains white. The cause of the reaction is still undetermined. It is probably the small amount of chloride in breast milk and consequently in the urine of the breast fed baby, which causes the silver nitrate to be present in excess. This excess is then acted upon by reducing substances in the urine and changed to metallic silver. Whatever the test depends on, it is apparently fairly reliable as Ostrowski obtained the following figures: 156 breast-fed babies, positive in 96.2%, negative in 3.8%; 30 bottle-fed babies, positive in 3.3%, negative in 96.7%; 78 babies fed on both breast and bottle, positive in 56.4%, negative in 43.6%.

ALIMENTARY ALBUMINURIA.

Hayashi⁵ has tested the nature of the albumin in the urine of 29 sick children and one sick infant, using the precipitin reaction with serums that had been sensitized to the proteins of beef, milk, egg white, and egg yolk. He found a positive reaction with the anti-milk serum in 5 cases, with the anti-egg white serum in 1 case, and with the anti-egg yolk serum in 3 cases; a total of 9 cases. These children, however, were all sick, although with different diseases, except that 2 of the 9 positive cases had pyelitis. Hayashi agrees with Hecker that "acute infectious predispose to alimentary albuminuria," and concludes that "not infrequently in cases of albuminuria there can appear in the urine unchanged albumin from the food ingested."

ORTHOSTATIC ALBUMINURIA.

Nicholson⁶ has made an excellent study of orthostatic albuminuria as it occurred among 189 healthy English school boys. He reports that 7.5% showed albumin on arising, 7% after breakfast, 10.7% after football, and 18% after a three-mile run. "Each test seems to have picked out a fresh set of subjects who were influenced by the conditions of the test." Adding all together, 28% showed albumin at one time or another. Bugge,⁷ however, found orthostatic albuminuria in 14.9% of 1076 school children in Christiania. It was much commoner among the girls than among the boys, the figures being 13.3% and 3.5% respectively. Nicholson⁶ was unable to discover any relation to the diet, to bathing, or to the height of the blood pressure. The administration of digitalis apparently increased the amount of albumin. The influence of position and of the muscular exertion of maintaining the body in equilibrium, he determined in an ingenious way. The boy was fastened flat in bed and then the head of the bed was very gradually raised, until after 1½ hours the boy had reached the vertical position. He was then released and allowed to sit quietly about the room. This was tried on two different boys. He found that "the mechanical raising of the body to the

vertical had a slight definite result; as it is quite certain that the albumin would not have appeared if the boys had stayed in bed in the ordinary way, we have a convincing proof that the mechanical raising of the body had a share in the albumin production." "In each case (after the boys were out of bed) the gentle movement necessitated by the maintenance of equilibrium, produced a large increase; after this the influence of the nervous system controlling equilibrium cannot be doubted."

Dietl⁸ believes that lordosis can cause sufficient stagnation in the renal vessels to induce albuminuria especially with the assistance of an unstable vasomotor system. Bass and Wessler⁹ have made a careful study of this theory and taken many blood pressure readings on children with orthostatic albuminuria. Unfortunately, "in spite of the apparent vasomotor insufficiency which many of these children showed, the blood pressure reactions both in the upright and recumbent positions and also after exercise, revealed no characteristic anomaly. Children with orthostatic albuminuria who showed marked cardiovascular symptoms could not be differentiated by means of blood pressure tests from the remainder of the group." They do not consider, however, that their findings have necessarily ruled out the hypothesis "that only those children react to lordosis by an excretion of albumin in whom an abnormal vasomotor system is unable to prevent congestion of the kidney," since their experiments were all made on the pressure in the brachial artery and the findings in the renal vessels of the same case might conceivably be different.

ORTHOSTATIC ALBUMINURIA AND TUBERCULOSIS.

It is claimed that orthostatic albuminuria is usually, if not always, a sign of tuberculous infection somewhere in the body. Reyher,^{10, 11} investigated 20 cases of orthostatic albuminuria and was in every case able to find tuberculosis. It was necessary to keep the children under observation for some time and to supplement the customary history and physical examination with a temperature record, x-ray plates, and von Pirquet test. Wendenberg¹² holds similar views, although he does not consider it an invariable sign of tuberculosis. Arnold¹³ believes that orthostatic albuminuria is merely a sign of a general infection and is by no means pathognomonic of tuberculosis. He found no orthostatic albuminuria in 44 cases of chronic skin tuberculosis, nor in 8 of psoriasis, while in 33 cases of early and untreated syphilis it was about as common as in the early stages of tuberculosis. Therefore it is not to be regarded as suggestive of incipient tuberculosis unless syphilis can be excluded. Sturm¹⁴ criticizes Arnold's conclusions because the latter was dealing with chronic skin tuberculosis, which is a localized process and can scarcely be expected to give the same results as pulmonary tuberculosis. Although admitting

that orthostatic albuminuria may occur in syphilis and other infectious diseases, he nevertheless asserts that it "is a valuable early sign of tuberculosis." He found it present in 12 out of 20 cases of phthisis.

ENURESIS.

Enuresis may be defined as lack of bladder control after the third year. It is a symptom and not a disease and should lead to an examination for retarded mental development, local malformations, ulcer at the meatus, phimosis, vulvitis, renal or bladder stone, tuberculosis of the bladder, thread worms, or anal fissure.¹⁵ Bogert¹⁶ regards it as a functional nervous disorder dependent upon chronic digestive disturbances. He analyzed the histories of 50 cases and noted "practically without exception gross errors in feeding." Consequently he restricts his treatment to the regulation of the diet and the general hygiene, the only drugs used being laxatives and intestinal antiseptics. He gives no figures but says he has obtained "a fair percentage of cures."

Schwartz,¹⁷ after a study of 246 cases, writes that "a review of the records does not bear out the assertion that chronic digestive disturbances are more frequent in cases of enuresis than in other patients. He also found "no connection between the tonsils and adenoids and the enuresis." "The degree of acidity of the urine bore no relationship to the severity of the incontinence," and although 70.9% of the specimens examined were acid, "the urine frequently varied in reaction on different visits" without any change in the symptoms. "Neither do the hemoglobin estimations point to anemia as an associated symptom." He found the following abnormalities of the genitalia: redundant prepuce, preputial adhesions, phimosis, hypertrophied clitoris; and the following under the head of the central nervous system: nervous, tic, chorea, imbecile, retarded mentality, indistinct speech, somnambulist, pavor nocturnus. He has nothing new to add to the treatment. In no instance did the customary hygienic and dietary measures effect a cure. The administration of atropine or thyroid was useless and alkalies seemed of doubtful value.

Simpson,¹⁸ on the other hand, in addition to regulating the general hygiene, uses drugs according to one of the following four methods:—

1. Urine normal. Tincture of belladonna, gr. x-xxv t.i.d.

2. Urine acid, full of urates, and of high specific gravity. Potassium citrate, gr. x, t.i.d., or enough to reduce the acidity, and then tincture of belladonna.

3. Urine alkaline, of low specific gravity and increased amount. All carbohydrate food must be prohibited. "If the urine is very alkaline acid sodium phosphate may be given; when the alkalinity has been reduced belladonna should be used. . . ."

4. Bacilluria, usually *B. coli*. Urotropin gr. v-x, t.i.d., often combined with potassium citrate.

If the treatment with belladonna fails he considers that ergot should be tried and also thyroid if the child is backward mentally.

Calhoun¹⁸ has developed a method of treatment which he used first among the recruits in the French army where it met with such success that some of his colleagues adopted it. He quotes Gaulejae as having obtained 50% of cures in treating 150 children with enuresis according to his method. He injects 40 to 60 c.c. of normal saline into the subcutaneous tissue of the perineum on each side of the median raphe. A single treatment is usually sufficient. The injection is made forcibly so that considerable distention results, "the aim being to act on the nerve terminals of the region by pressure." In some way this stimulus reinforces the sensation of a distended bladder, so that the patient is waked out of a sound sleep by the desire to urinate.

NEPHRITIS.

Heubner¹⁹ found only 73 children with chronic kidney disease in a series of 17,000 cases. He makes no attempt to use the customary adult classification, but groups them as follows:—

1. Chronic hemorrhagic nephrosis—the commonest, consisting of almost $\frac{1}{2}$ the cases. It is characterized by edema and by bloody urine with albuminuria and casts. The duration is for years, with a tendency to grow worse.

2. Very similar to the first group, but without the hemorrhage. The course is more rapid, and death usually ensues after several months.

3. There was 1 case of a true contracted kidney.

4. There were 6 cases of pyelitis.

5. A group of mild nephroses following the acute infections. Frequently there are no symptoms, although the urine contains albumin and casts. It is serious only if after a second infection it passes over into one of the other types.

6. Practically a still milder form of the preceding group, ending in recovery.

Castro²⁰ adds to this classification a type which he labels erythrocyturia minima. It consists of the unexplained appearance of small numbers of red blood cells and leucocytes in the sediment of otherwise normal urine during an attack of one of the milder infections, or after vaccination, or the injection of tuberculin. He considers "that in addition to the factor of infection a constitutional predisposition must be hypothesized similar to that which is agreed on for orthostatic albuminuria."

Frank²¹ has studied the autopsy protocols of 452 infants, finding only 4.86% of acute nephritis. These were classed as follows:—

1. Exudative Type, predominantly hemorrhagic, purulent, with leucocytic infiltration and of lymphocytic character, 16 cases.

2. Interstitial Type, 4 cases.

3. Mixed Type, 2 cases.

The comparative frequency of the hemorrhagic type is of interest here. He considers it "due to the abnormally great permeability of the blood vessels in the first year of life."

Stavsky²² has reported 2 cases of Heubner's paedonephritis levis in which "no treatment or lack of treatment has modified conditions in the least." He urges that the children instead of being kept in bed should be allowed to lead a normal life, except that food which is liable to irritate the kidneys should be excluded from the diet.

Noeggerath and Zondek²³ have applied the modern tests of renal function to 6 children with nephritis and to several healthy controls. All the children were first put on a standard diet, which for a boy of 10, weighing 28.8K, consisted of 500 c.c. milk, 50 c.c. sugar, 50 gm. unsalted bread, 10 gm. unsalted butter, 100 gm. potatoes, 80 gm. carrots, 80 gm. apples, 250 c.c. tea, 100 c.c. coffee, 400 c.c. water, 15 c.c. lemon juice. This totals 1436 calories, 26.04 gm. albumin, 1.121 gm. salt, and 1061 c.c. water.

"The tests were made by superimposing on this standard ration varying amounts of salts, from 1 to 5 gm. a day, and varying amounts of a commercial food representing 67.4% albumin, 0.2% salt, and no extractives." The authors concluded "that the albumin content and the sediment of the urine are far from reliable criteria as to the functional capacity of a child's kidney. They may be apparently normal while the child is unable to tolerate the salt and albumin of the normal diet for his age. It sometimes happens that the tolerance for salt becomes upset when albumin beyond what he can tolerate is being taken, or vice versa."

In the treatment of the severe type of acute nephritis in children they made use of a diet exclusively of sugar, and later of drawn breast milk mixed with oatmeal gruel.

Reinike²⁴ reports that, by the use of polarized light lipid substances can sometimes be detected in the urine sediment. Their occurrence is an "indication of the destruction of epithelial kidney tissue." He found lipoids in 8 out of 100 cases, in 4 of these only one drop on a single occasion. Of the other 4 cases, 2 were without doubt a chronic degenerative nephrosis, and in the other 2 "it was the discovery of the lipoids which suggested the severity of the disease before the clinical course allowed an exact opinion." He never found lipoids in healthy children, or in acute nephritis or orthostatic albuminuria.

STONE.

Ollershaw²⁵ has reported 2 cases of renal calculus in children, one in a girl of three years, the other in a boy of eight years. In both the symptoms had begun at least a year before operation, although the kidneys had not yet become infected. The stones were single, as was shown

by x-ray, and were easily removed at operation. In neither case was there any recurrence. He believes that renal stones are probably commoner in children than has been suspected, and that they should be looked for most carefully in every case of hematuria or gravel or enuresis.

Collins,²⁶ on the basis of a review of the literature, concludes that "calculi discovered in older children or in adult life frequently originate in infancy or childhood." Apparently most cases in early life are found accidentally at autopsy, and "there is a paucity of case reports of renal stone in infants discovered and treated surgically." He adds one case to those already reported, that of a sixteen months' old boy with a stone impacted at the tip of the urethra. In addition he was able to demonstrate stones in both kidneys, but was not allowed to operate. He found that "diseases of an infectious nature occur in association with calculus and hydronephrosis in 65% or 107 cases" and that "diseases of the respiratory tract are associated with urinary stone or hydronephrosis most often." The treatment is clearly surgical as soon as the diagnosis is made.

UTERINE HEMORRHAGE OF THE NEWBORN.

This condition is not to be confused with precocious menstruation or with hemorrhagic disease of the newborn. It usually appears about the fifth to the seventh day after birth, too early for precocious menstruation, and never recurs. There is no bleeding from other parts of the body. The total amount of blood lost is very slight. In none of the reported cases have there been any of the secondary signs of sexual activity, such as engorgement of the breasts, growth of axillary or pubic hair, etc.

The condition is not a common one, the figures which Zacharias²⁷ has obtained from the literature and from his own investigations varying from 0.12% to 2.59% of female births. The bleeding appears on the fifth to seventh day, occasionally earlier or later, and lasts one to two days. It is not serious, being usually nothing more than a stain on the diaper, and requires no treatment.

The cause is so far uncertain. Juda²⁸ and Zacharias²⁷ both uphold Halban's theory, which is in brief that the internal secretion of the placenta which causes the enlargement and increased blood supply of the maternal uterus, may enter the fetal circulation and thus produce an analogous condition in the uterus of the child. The uteri of newborn infants show on histological examination all degrees of engorgement, even up to the point of hemorrhage into the uterine cavity. Zacharias adds, however, that in all his cases the infants were above the average weight and suggests that the additional compression to which they were subjected during delivery may have produced an increased liability to genital hemorrhage.

PYELITIS.

Thomson²⁹ discusses the mode of infection in an excellent paper based on 71 cases of colon infection of the urinary tract in his private practice. He believes that the bacilli may reach the kidneys by the blood stream, the lymphatics, or the urethra and ureters. "If the virulence of the organisms has been increased by morbid processes in the intestine or otherwise, or the normal resistance of the tissues lowered by local or general disease; or perhaps if there has been some retardation of the flow of urine, then more or less violent inflammation may be set up." In analyzing his cases he found that 79% were girls; that diarrhea at onset was commoner in infants than in children, and in boys than in girls; that under six months of age more boys than girls were affected; that rigors at onset are rare in boys and comparatively common in girls; and that the course of the disease is more severe in boys and more apt to terminate in a fatal pyelonephritis. He decided that "the great preponderance of female patients forces us to the conclusion that ascending infection by way of the urethra must be a common occurrence; and the excess of girls over boys probably represents the frequency with which urethral infection takes place. It seems very unlikely that colon bacilli can force their way up the lumen of the male urethra. The greater prevalence of antecedent diarrhea in boys would probably cease to exist if we were able to subtract from the list of girls the primary cases infected per urethram. The frequency of pyelonephritis in the male sex may be explained by the infection having usually in them passed straight from the bowel to the kidney and pelvis and not having ascended from below. The facts that rigors are so very rare in acute pyelitis in boys and in pyelonephritis in both sexes, while they are so common in acute pyelitis in girls (in whom we suspect an ascending infection) suggest the idea that the ureters may be the particular portion of the urinary tract from irritation of which a rigor most readily arises. The frequency with which rigors are met with in ureteral calculus may be held to support this view."

Somewhat similar views are held by Wyman,³⁰ who, from a study of 65 cases at the Children's Hospital in Boston, concludes that the ascending route is the common one in girls and the hematogenous in boys, while the transparietal is rare in both sexes.

Cannata and Caronia³¹ emphasize the necessity of preventing the early infections. They regard habitual constipation as dangerous because there is usually elimination of bacteria by way of the urinary apparatus. They, as well as Stiner,³² mention chilling as a common exciting cause.

Langstein³³ has reported a fatal case of pyelitis in which the infecting organism was Friedländer's bacillus.

Kowitz³⁴ reports a series of 40 cases consisting

of 17 males and 23 females. There was a marked seasonal variation, the disease being most common in September. He believes that pyelitis is a hematogenous infection following the digestive disturbances of the summer.

Freeman³⁵ endeavors to draw a line between a normal and a pathological number of pus cells in the urine. According to him "1-2 leucocytes in a D field (Zeiss) of precipitate (of centrifugalized urine) from a female baby does not indicate pyelitis. That number in a male baby, or more in a female baby, should render the diagnosis suspicious." F. H. Smith³⁶ finds that as few as 3 pus cells to the 1/6 field in either sex may cause the most severe symptoms.

A hemorrhagic type of pyelitis has been described by Langstein.³³ The sediment consists of "many red blood corpuscles, only scattered leucocytes, and perhaps here and there a cast. At the time it is difficult to decide whether this is the picture of a hemorrhagic nephritis, a calculus, or a beginning pyelitis."

The disease may last untreated for several years, showing either no symptoms or occasional exacerbations.^{29, 35, 37, 38, 39} With correct treatment at least 90% of the patients recover. The condition may lead to a contracted kidney or to a nephrosis.³³ "Before pronouncing the patient cured the urine should not only show an absence of organisms and of pus cells, but should also be culturally free."³⁸

Little new has been written about treatment. Alkalies are advocated by Thomson²⁹ and Marsh.²⁸ Wyman³⁰ favors changing the reaction of the urine back and forth by the alternate administration of potassium citrate and sodium benzoate. Freeman³⁷ admits that alkalies will control some cases, but considers them markedly less efficient than other methods of treatment. Langstein³³ regards the alkaline treatment as useless.

There is similar disagreement about the value of the "urinary antiseptics." The upholders of hexamethylenamine are Freeman,^{35, 37} Wyman³⁰ (as second choice), and Cannata.³¹ Langstein³³ prefers salol. Marsh,²⁸ Thomson,²⁹ and Kowitz³⁴ are skeptical as to the value of any urinary antiseptic.

Freeman³⁵ reports that vaccines will relieve symptoms but not cure the pyelitis. "The child loses its fever and will increase in weight and seem perfectly well, but when the urine is examined one finds the same pus and bacteria as before." The other authors are either skeptical as to the value of vaccines,^{30, 34, 35, 40} or consider them useless.^{29, 33, 39}

VAGINITIS.

There have been a number of investigations,^{41, 42, 43, 44, 45} into the sources of infection in vaginitis, the general tendency of which, notwithstanding the great importance of hospital and institutional epidemics, is to place the ultimate responsibility further back, in the home,

the school, and the street or play-ground. In from 30 to 50% of the cases the infection has come from other members of the family, while hospital infection is given as only 3 to 30%. The remaining cases seem to acquire the disease from their playmates, either through indulgence in bad habits or innocently from infected toilets.

Prophylaxis is as much a social as a medical problem, but no board of health has as yet dared to undertake it. Goldwater⁴⁶ of New York has written an interesting report from the health officer's view point in which he offers no solution. Other authors,^{41, 43} have suggested various extreme and untried measures. All^{41, 42, 43, 44, 45, 47} agree in keeping the children out of school for a few weeks and in warning teachers and school nurses when they go back that they are not to use the common toilet.

The diagnosis in doubtful cases is greatly helped by the use of a urethroscope through which smears may be obtained from the vaginal vault and cervix.^{43, 45}

The most important part of the treatment is to keep the child in bed for the first few weeks and to use every means to improve her general condition. Opinions vary greatly as to the efficacy of local treatment. Kerley⁴⁸ and Hamilton⁴⁹ merely keep the patient clean and dry. Others^{42, 44, 47} follow a cleansing douche by the instillation of some silver preparation. Barnett⁴³ uses a permanganate douche and follows it three times a week by an endoscopic treatment of the cervix and vagina with Lugol's solution. Rubin and Leopold⁵⁰ consider the use of the electric lighted female urethroscope essential in treating the disease.

The advisability of using vaccines is still disputed. Hamilton⁴⁹ is "still enthusiastic in the treatment of recent cases by vaccines." Comby and Condat⁵¹ also speak favorably. Spaulding⁴⁴ has tried them out in 35 cases in addition to the local treatment and feels that they are possibly "an additional factor for good." Barnett,⁴³ Hamburger⁵² and Heyman and Moos,⁵³ however, consider vaccines useless.

Proof of the cure of the disease is difficult to obtain. Spaulding⁴⁴ believes that the disease may be latent for "as long as 18 months" and "that the most efficient treatment does not insure a permanent cure." Mattisohn⁵⁴ reports similar findings. G. G. Smith⁴⁷ has used the complement fixation test and finds it of considerable value for the purpose of establishing a cure. He writes that "if after three or more months, during which frequent smears from the depths of the vagina have contained no pus, and all other signs of the infection have disappeared, a discharge containing gonococci recurs, we believe that this attack is frequently a reinfection, very possibly from the same source as the first."

GONOCOCCUS INFECTION IN BOYS.

Two interesting cases of gonococcus infection in boys have been reported, one of urethritis in

a boy of 17 months,⁵⁶ and the other of arthritis in a boy of two and one-half years.⁵⁶ In the latter case gonococci were obtained in pure culture from the purulent joints and also from the urethra, which, however, showed no signs of disease even on careful examination.

TUBERCULOSIS.

Renal tuberculosis in children is a very rare disease. Oraison⁵⁷ reports three cases, all in girls, bringing the total number of reported cases up to 51. One of his patients had a severe Potts disease, was not operated on, and died; the other two had nephrectomies; one apparently recovered and the other was lost sight of. Roehrer and Ferron⁵⁸ report a case, also in a girl, in which the offending kidney was removed with resultant cure.

Primary genital tuberculosis is also rare. Lyons⁵⁹ reports three cases in small boys. In two of these the infection was in the epididymis and the patients appeared to be in perfect health. In the third the prostate and seminal vesicles were found infected and the boy presented a typical tuberculous appearance. Lyons concludes that in these cases tuberculosis of these organs is usually the only focus in the body and that therefore operation may produce a permanent cure.

Graefe⁶⁰ in an analysis of necropsy protocols found 19 cases of genital tuberculosis in girls under 15 years. The lesions of the genitalia were invariably secondary to tuberculosis elsewhere. The tubes were the favorite site of infection.

Holt⁶¹ has reported a case of milary tuberculosis following a ritual circumcision. He gives an abstract of the 40 cases already reported and says that of the 41 patients, 16 are known to have died, 7 are tuberculous, in 12 the final results are not known and only six are stated to have recovered.

Champtaloup⁶² reports a similar case from New Zealand, except that the operator was a physician who has since died of laryngeal tuberculosis. This patient was treated with tuberculin and when seen eight months later was the picture of health.

RHEUMATIC ORCHITIS.

Bass⁶³ describes a boy two and one-half years old who developed erythema nodosum and torticollis, and four days later, while under treatment with salicylates, a sudden swelling of the scrotum. The scrotum was hot, edematous and dusky in color, and the left testicle was enlarged and exquisitely tender while the right was normal. The condition quickly subsided and a month later there was "no atrophy of the testis."

Reports of Societies.

THE BOSTON SURGICAL SOCIETY.

STATED MEETING (CLINICAL) HELD ON MONDAY, APRIL 5, 1915, AT THE MASSACHUSETTS GENERAL HOSPITAL.

GASTRIC CANCER.

DR. C. A. PORTER did a partial gastrectomy for gastric cancer.

CANCER OF CERVIX: OPERATION: PALLIATIVE LIGATION OF THE INTERNAL ILIAC ARTERIES AND CAUTERIZATION OF THE CERVIX.

DR. FARRAR COBB presented and operated upon this case.

McG., forty-six, white, widow. Symptoms: For two years irregular catamenia, occasionally profuse hemorrhage. For five months weakness and continuous foul vaginal discharge with constant pain low in the pelvis, dull, not severe.

Examination showed vagina filled with fungating, cauliflower-like ulcerated mass. Induration in both broad ligaments.

Operation April 5th. Median suprapubic incision. Disease well into the broad ligaments. Right internal iliac artery ligated with silk. On the left side dense adhesions between an old pus tube and the sigmoid flexure made ligation of the artery too dangerous. The abdominal wound closed without drainage. Patient placed in lithotomy position and cervix thoroughly cauterized.

(This patient made an uneventful convalescence, and had no further pain while in the hospital. No hemorrhage. Discharged from the hospital on April 19th.)

A CASE OF DUODENAL ULCER AND CHRONIC APPENDICITIS.

DR. CHARLES L. SCUDDER presented and operated upon a case with the above diagnosis and the appended history:

Two weeks ago the patient, a married woman of 25 years of age, entered the hospital complaining of stomach trouble. Her family history was negative. Her past history showed repeated attacks of tonsillitis. She had been troubled with constipation for four years.

For three years she had had attacks of epigastric pain from four to five times a day, lasting about twenty minutes each time. The pain was gnawing and burning in character and was relieved by lying down and by soda. The pain was severe enough to double her up. During the present attack she has vomited all solid food. About half an hour after meals she becomes nauseated and vomits. Three weeks ago she vomited a small amount of blood. The pain was inconstant during the first two years but has become pretty constant the past year. She has lost 50 pounds in weight in three years.

Physical examination was negative excepting for slight tenderness in the epigastrium. Peristalsis was visible.

Two x-ray examinations were made. The first showed adhesions obstructing the duodenum. The second was interpreted as probable duodenal ulcer and possibly adhesions. There was a question of stones in the gall-bladder.

The Wassermann examination of the blood was negative. The urine was negative. The blood tests of the stool were repeatedly negative. The hemoglobin was 80%.

The tube examination showed a fasting content of 60 c.c. of green, cloudy fluid. There was free HCl and the test for blood was positive. The test meal showed 105 c.c. of cloudy white material. Free HCl was .18% and the total acidity was .26%.

The history and the x-ray in this case are suggestive of duodenal ulcer, and the x-ray is also somewhat suggestive of gall-stones.

Exploration showed an induration just below the pyloric ring in the first portion of the duodenum posteriorly. No stippling was seen. There was no other pathology, both the stomach and gall-bladder appearing normal. The pyloric region of the ulcer was infolded and a posterior gastroenterostomy was done. Under a separate incision the appendix was found covered with a veil, thinned out and bound down by adhesions. An appendectomy was done.

Two weeks following the operation the patient was discharged from the hospital looking and feeling well. She had a good convalescence, with no complaints of any kind.

REMARKS.

I believe that given findings such as in the case before us, an uncomplicated duodenal ulcer, a posterior gastroenterostomy with infolding of the duodenal region temporarily and partly to obstruct the passage of food is sufficient treatment for the ordinary case of duodenal ulcer. I personally believe that all procedures for causing obstruction including section of the pylorus should be reserved for those cases which require a second operation. Until we are more informed about the cause of ulcer and the real influence which a gastroenterostomy has upon the healing of a duodenal ulcer, this seems to me the wisest attitude to take in the treatment of these cases.

The red stippling sign was absent in this case, probably because the lesion was posterior and was not near enough to the surface to be seen. I believe the red stippling sign is an important sign and as times goes on that it will aid the surgeon in distinguishing cancer from chronic ulcer.

CHOLECYSTECTOMY FOR CHOLELITHIASIS.

DR. LINCOLN DAVIS detailed the history of this case and performed the operation.

RENAL STONES: RENAL CYST: OPERATION.

DR. HUGH CABOT operated on this interesting case. He felt before operation and proved by operation that the shadows shown in the kidney region in the x-ray plate were not stones but calcified glands. The stones which were found at operation were not shown in the plate. In addition to the stones there was a cyst of the lower pole of the kidney as large as an English walnut. Dr. Cabot went into the differential diagnosis of the case very carefully, and he stated that preoperative diagnosis was probable hydronephrosis.

ABDOMINAL PAIN: EXPLORATORY LAPAROTOMY.

DR. HUGH WILLIAMS presented a case in which every effort had been made to establish a diagnosis of the cause of the pain in the upper abdomen. The probable diagnosis was cholelithiasis or cholecystitis. The exploratory operation was negative in its disclosures.

SARCOMA OF THE SCAPULA: INTERSCAPULO-THORACIC AMPUTATION.

DR. FARRAR COBB presented the patient.

M. C., 48, white, married. Symptoms: For two months pain in left shoulder, limitation of motion in the left arm with the appearance of new growth. Shoulder girdle amputation was performed because of the large sarcoma occupying the region of the scapula and point of the shoulder. Previous to the operation the patient had indirect blood transfusion. Patient suffered no shock at the operation. The wound healed by first intention. Operation done March 11, patient discharged from the hospital March 30.

POPLITEAL ANEURYSM; LIGATION OF THE POPLITEAL ARTERY; GANGRENE OF THE FOOT.

DR. CHARLES A. PORTER presented this case. A Matas operation was impossible; hence ligation of the artery was done; a limited gangrene of the foot followed.

SYPHILIS AND CARCINOMA OF THE UPPER JAW.

DR. PORTER then exhibited a patient with a tumor of the upper jaw. An outline of the history was given and Dr. Porter asked for opinions as to the probable diagnosis and as to treatment. He said that a microscopic examination of tissue excised showed both syphilis and cancer.

ACTINOMYCOSIS OF ABDOMINAL WALL.

DR. PORTER showed a man with a slowly healing actinomycosis of the abdominal wall.

INOPERABLE SPINA BIFIDA.

DR. PORTER also presented an infant showing an apparently inoperable spina bifida.

CENTRAL GIANT CELL SARCOMA OF UPPER END OF ULNA.

DR. C. C. SIMMONS presented this case:—

The patient is a colored man forty years old. He has always been in fair health. Denies venereal. Five years ago he was in the Boston City Hospital for five weeks for pleurisy and the chest was tapped once. He has been working ever since.

Twenty-eight months ago he fell, striking on the right elbow. Following this he began to have pain in the elbow, intermittent and not very severe. He first noticed a swelling eighteen months ago, and this has slowly increased, gradually limiting the motions of the joint.

Physical Examination. Negative except as follows: There was evidence of an old process in the base of the right lung, demonstrable by physical signs and x-ray. There was a bony tumor occupying the upper four inches of the right ulna about the size of a large orange. This was hard, with soft areas, circumscribed and not tender. It mechanically limited the motions of the joints. There are no axillary glands. The Wassermann was negative. Blood picture not remarkable.

X-ray showed the upper four inches of the ulna distended to the size of an orange by a tumor. The outer walls were thin bone and the cavity was traversed by many fine bony trabeculae.

Operation. Resection of the upper third of the ulna was accomplished without much difficulty. The triceps tendon was sutured to the fascia of the forearm, and an orbicular ligament was made from fascia to prevent the head of the radius from dislocating forwards.

Convalescence uneventful.

Pathological Report. Giant cell sarcoma.

The giant cell central sarcoma is the least malignant type of bone sarcomata, practically never forming metastases. Some observers recognize two forms, one of which is benign, and the other forming metastases. If recurrence takes place it usually does so locally. Resection is the operation of choice and amputation should be performed only under exceptional circumstances.

At present, ten days after operation, it would appear that the elbow will be a fairly useful joint. It may be possible, however, at a later date to do a bone graft to fill in the defect caused by the removal of the ulna.

DUODENAL ULCER; PERFORATION; TREATMENT OF DUODENAL FISTULA.

DR. DANIEL F. JONES reported a case of perforated duodenal ulcer.

The patient, a man of 65, developed a duodenal fistula, after drainage of an abscess in the region of the head of the pancreas. In poor condition, and septic, before the fistula developed, he rapidly ran down hill, as all food taken by mouth came out the fistula. The walls of the wound, and the skin, were rapidly digested. At the end of ten days, the patient was almost moribund, with no pulse whatever, that could be felt at the wrist.

A Witzel jejunostomy was done under local anesthesia, in order to nourish the patient, and give him fluid. An hydraulic siphon was then connected up with a catheter, which lay in the wound. A bottle was interposed, between the wound and the siphon, to collect the digestive fluids. All dressings were removed, and the skin covered with zinc oxide ointment.

The patient remained almost pulseless for twenty-four hours, then gradually improved.

The wound leading to the duodenal fistula was kept absolutely dry, by the siphon, and as fast as the digestive fluids were collected in the bottle they were put into the jejunum, through the jejunostomy.

Within one week the fistula, which was a very large opening into the bowel, was closed, and the patient's condition was much improved. Five days later an attempt was made to feed the patient by mouth, but the symptoms of duodenal ulcer were so severe, including vomiting of coffee ground material, the feeding by mouth was stopped for two weeks, and the feeding by jejunum continued. At the end of this time, the patient took his nourishment without discomfort, or other symptoms, and has now entirely recovered.

Attention is called to jejunostomy in this condition, as being more sure and more satisfactory, than a gastro-enterostomy, which is frequently done in cases of injury to the duodenum. The siphon, as used in this wound, will prove of the greatest value. I am sure, in many fistulae, such as those which occasionally follow perforated ulcers, biliary fistulae, all small intestine fistulae, and even suprapubic cystostomies.

DR. HUGH WILLIAMS spoke of a similar case and a similar use of the siphon. He exhibited an electric double-suction pump designed by his chauffeur for the purpose.

DOUBLE EXOPHTHALMOS WITH OPTIC NEURITIS, A SMALL GOITRE AND SLIGHT SIGNS OF HYPERTHYROIDISM.

DR. LINCOLN DAVIS presented and discussed this case. The diagnosis lies between Graves' disease and a possible new growth in the sphenoidal region.

DR. GEORGE S. DERRY saw the case in consultation and reported that the patient, a female, 54 years old, noticed in October, 1914, some protrusion of her left eye. This gradually increased, and a fold of conjunctiva below the eyeball became edematous and projected forward between the closed lids.

Four weeks ago, the protrusion of the left eye appeared to subside, and the right eye then began to protrude a little, accompanied with swelling of the fold of conjunctiva.

The proptosis is now considerable, and about equal on both sides. Limitation of motion of the eyeballs downward and to the left; slight limitation upward.

Right eye now tends to diverge. Right cornea slightly hazy and epithelium wrinkled. Right optic nerve head shows some neuritis.

Left cornea and media normal. Very marked optic neuritis, with swelling of the disc and congestion of the veins. Several hemorrhages.

Pupils equal and react.

Vision right, 20/100.

Vision left, 20/70.

Patient has a palpable thyroid, slight tremor of the hands, and the pulse-rate has at times reached 160. At present it runs between 80 and 90. Blood pressure, 200. Wassermann negative.

Neurological examination, with reference to intracranial pressure, negative.

Numerous nasal examinations negative.

Various possible diagnoses: a new growth far back in the nose, exophthalmic goitre, disease of the posterior ethmoid cells or sphenoid sinuses. Thus far, it has not been possible to make a diagnosis.

Optic neuritis is extremely rare in Graves' disease.

Fields of vision have been taken, but throw no light on the condition.

Case is brought before you in hope of receiving suggestions as to diagnosis and treatment.

SEPARATION OF THE LOWER EPIPHYSIS OF THE FEMUR WITH DISLOCATION.

DR. C. L. SCUDDER presented a boy, 9 years old, who, while stealing a ride, caught his foot in the spokes of a revolving wheel, sustaining an injury to the left leg, for which he was immediately brought to the accident room of the hospital.

Examination found a well developed and nourished boy in great pain. All findings were negative excepting for the left leg, which was displaced inward with inward rotation of the foot. There was considerable shortening and great tenderness. The lower end of the femur could be felt just beneath the skin at the outer side of the leg just above the knee. All motions of the leg caused extreme pain. The leg was held in median flexion. No extension was possible because of the great pain. There was no ecchymosis or break of the skin, and the swelling about the knee was considerable. The leg was placed in pillow and side splints.

The X-ray which was taken at entrance showed a separation of the lower epiphysis of the left femur with dislocation of the epiphysis forward under the patella.

Three days after the accident I operated upon this patient. Two lateral incisions were made 5 inches long. The displaced epiphysis was exposed through these incisions. Two strong Lambotte hooks were placed on the edge of the displaced epiphysis and by traction upon these hooks, by traction upon the leg, and by pressure over the lower end of the femur posteriorly, the separated epiphysis was replaced in its normal position. The two lateral incisions were closed by suture and the leg flexed firmly upon the thigh and held in this position by means of a plaster bandage.

The x-ray subsequently demonstrated that the epiphysis had been replaced. A report six weeks later finds that the boy is moving his knee through an arc of about 20 degrees, is having gentle traction made upon the leg, massage to the knee and active movements. He is gradually gaining the full use of the knee.

REMARKS.

It has been suggested by Binney and others that in certain cases of separation of the lower epiphysis of the femur it may be necessary to insert a steel pin through the epiphysis into the shaft in order to prevent a slipping of the epiphysis after reduction. In this case there was no tendency to slipping of the fragments upon the shaft, while the acutely flexed position of the knee was maintained. The only advantage that a pin might have been to this boy is that had it been used he might have been allowed earlier freedom in the movement of the leg, and so he would have gotten about a little bit sooner.

OPERATIVE PROCEDURES UPON THE KNEE-JOINT.

DR. E. G. BRACKETT showed a series of cases illustrating the ease and success with which the cavity of the knee-joint can be explored or operated upon through a median incision of the patella. Both tendons should be exposed freely so that they may be well seen and that an exact median incision may be made in the patella. The upper end of the skin incision should slant slightly outward; the bone should be cut through cleanly, but the tendons should be only nicked. Do not displace very much the fascia and tendon on the patella.

The greatest possible care in asepsis should be exercised. The closure is entirely by silk. The joint is completely immobilized for not more than three days. Passive motion is instituted after the first week or ten days. Weight-bearing is allowed in from four to six weeks.

Book Reviews.

Essentials of Medical Electricity. BY GEORGE KNAPP ABBOTT, A.B., M.D. Illustrated. Philadelphia and London: W. B. Saunders Company. 1915.

This manual for medical students and nurses aims to present the principles of electrotherapy in suitable form for elementary instruction and yet with sufficient scientific completeness to cover the fundamental facts of its clinical application. The subjects of galvanic, faradic, sinusoidal and static electricity are successively considered with chapters on electrolysis cataphoresis, electrotonus, electrodiagnosis and high frequency currents. The work is illustrated with 87 text cuts illustrating apparatus and modes of application. The attempt to make the text easily comprehensible is, in a large measure, successful though the subject requires a knowledge of at least elementary physics for its satisfactory understanding. At the close of each chapter is a series of useful questions for review. It would seem that the book is much more likely to be of value in medical schools than in training schools for nurses.

Local and Regional Anesthesia. With Chapters on Spinal, Epidural, Paravertebral, and Parasacral Analgesia, and on Other Applications of Local and Regional Anesthesia to the Surgery of the Eye, Ear, Nose and Throat, and to Dental Practice. By CARROLL W. ALLEN, M.D., instructor in Clinical Surgery at the Tulane University of Louisiana, New Orleans; Lecturer and Instructor in Genito-Urinary and Rectal Diseases at the New Orleans Poly-clinic; Visiting Surgeon to the Charity Hospital. With an Introduction by RUDOLPH MATAS, M.D., Professor of General and Clinical Surgery at the Tulane University of Louisiana, New Orleans, etc. Illustrated. Philadelphia and London: W. B. Saunders Company. 1914.

This is a well-printed book of 600 pages covering every portion of the field of local anesthesia. Under this head, as is apparent from the title, Dr. Allen includes chapters on spinal and sacral anesthesia.

This is the book of an enthusiast, who has much practical use of the methods he describes, and has covered the literature upon the subject in a most extraordinary manner. It is unfortunate, indeed, that his extensive bibliography is eliminated from the book, even for the excellent reason of avoiding undue bulk. The author has been successively a student, assistant and associate of that brilliant, untiring and original surgeon, Matas of New Orleans, who nearly two decades ago planned and actually began a book on this subject. It will be somewhat of a surprise to a good many young surgeons to discover that Matas was one of the greatest and earliest investigators of local anesthesia in this country. His name has usually been associated with entirely different branches of surgery. His introduction is interesting and contains a brief summary of the various and unusual procedures which he carried out in those early years. Dr. Allen most enthusiastically credits his teacher with not a few of the great advances made in the early days of local anesthesia.

The book is composed of twenty-three chapters, beginning with history; then follows consideration of nerves and their sensations; osmosis and diffusion; various anesthetics; their dangers; technic; indications; and a detailed description of the methods in use upon the various anatomical areas of the body. As already noted, spinal, epidural, paravertebral, parasacral anesthesia, and the anesthesia of the organs of special sense and the teeth, are included in the single volume. The author quotes freely from Braun, to whom he makes special acknowledgment. The book is marked by that thoroughness which it is customary at present to describe as German, and fortunately lacks the unnecessary prolixity of many German treatises.

It is superfluous to comment on the fact that the field of local anesthesia is limited at present only by infancy, and by the surgeon. There are few operations indeed which have not been successfully carried out under local anesthesia. It certainly does require perseverance and precise anatomical knowledge, but it is worthy of more general attention than has yet been paid to it in America. The book seems admirable and is unhesitatingly recommended.

The Gold-Headed Cane. By WILLIAM MACMICHAEL, M.D. New York: Paul B. Hoeber. 1915.

This new American edition opportunely recalls to general professional familiarity a classic collection of medical essays written with the charm of a century ago and based on the story of the gold-headed cane carried successively by Drs. Radcliffe, Mead, Askew, Piteairn and Bailey, whose biographies, as supposedly told by the cane, compose the substance of the book. The cane in question was deposited by the widow of its last possessor in the new college of physicians of London in 1825. Dr. Maemichael's felicitous exposition of its history was first published in 1827 and a second edition appeared the following year. In 1884 was published a third edition, in which the editor, Dr. William Munk, wrote a continuation of the narrative in excellent imitation of Maemichael's style, bringing the story down to the year 1871. This present fourth edition follows the text and illustrations of the second and represents the work as left in finished form by the author. In a charming preface, Dr. Francis R. Packard of Philadelphia sketches the life of Maemichael and the history of his work and of the cane. Sir William Osler in his introduction briefly comments on the lives of the cane's possessors and points out that this fourth edition is published as a memorial to Dr. Radcliffe on the two hundredth anniversary of his death. A wholesome interest in the history of medicine and of its famous men is being fostered in these days as a desirable counteracting agent to the excessive scientific tendencies of the time, and few works could form a more appropriate introduction to such a study than this story of the lives of five of the more eminent British practitioners of the seventeenth and eighteenth centuries.

Transactions of the American Climatological and Clinical Association. VOL. 30. Philadelphia. 1914.

This volume records the proceedings of the American Climatological Association at its thirty-first annual meeting in Atlantic City, N. J., in June, 1914. It includes the president's address by Dr. J. M. Anders of Philadelphia, and a series of 23 papers presented at the ses-

sions of the meeting. Among these may be noted those by Dr. Edward O. Otis on "Unsolved and Debatable Problems in Tuberculosis;" by Dr. Arthur K. Stone on "Subnormal Temperature in Tuberculosis;" by Dr. Cleveland Floyd on "The Interrelationship of Pleurisy and Empyema;" by Dr. Guy Hinsdale on "Atmospheric Air in Relation to Tuberculosis;" and by Dr. Nathaniel K. Wood on "Percussion of the Lungs." Many of the articles are well and abundantly illustrated by attractive, full-page plates.

Infection and Immunity. A Textbook of Immunology and Serology for Students and Practitioners. BY CHARLES E. SIMON, B.A., M.D., Professor of Clinical Pathology and Experimental Medicine, College of Physicians and Surgeons, Baltimore. Third edition. Svo. 351 pp., illustrated. Philadelphia and New York. Lea & Febiger. 1915.

The reviewer has had occasion to express his appreciation of an earlier edition of this work. The author has achieved his purpose in presenting a lucid and easily readable exposition of the subject of "Immunology and Serology." Practical applications are given with sufficient detail and clearness and are satisfactorily illustrated. The work is without undue pretense and contains an adequate bibliography appended to each chapter. It is to be particularly recommended for students and beginners in laboratory methods.

Materia Medica and Therapeutics. BY LYNETTE A. PARKER, B.Sc., R.N., Instructor in Nursing and Health, Teachers' College, Columbia University. New York. Philadelphia and New York: Lea & Febiger. 1915.

This textbook for nurses aims to present the use of drugs from a scientific basis and an effort has been made to give only the important and practical points which form a foundation for the intelligent handling of drugs but not for their prescription. Detailed descriptions of the physical properties of the drugs have in many cases been omitted. After a series of initial chapters on weights and measures, solutions, pharmaceutical preparations, definitions, history, administration of medicines, toxicology, acids and alkalies, salts and the active principles of medicinal plants, the principal drugs of the pharmacopoeia are considered in groups according to their action on various anatomic and physiologic systems and functions of the body. There are also chapters on prescriptions, on habit-forming drugs and on psychotherapy, hydrotherapy, electrotherapy, serotherapy and radiotherapy. A large amount of useful and available information is thus made accessible to

nurses within the relatively brief space of 300 pages. The work is well illustrated with 29 engravings and three attractive colored plates. It presents a rather dry subject in interesting and original form.

Bodily Changes in Pain, Hunger, Fear and Rage. BY WALTER B. CANNON, M.D., George Higginson Professor of Physiology in Harvard University. New York and London: D. Appleton & Co.

In this monograph the author presents an account of his recent researches into the function of emotional excitement, with especial regard to the four primitive human and animal experiences of fear, rage, pain and hunger. These investigations into the bodily changes occurring in conjunction with these emotions have been conducted during the past four years at the Harvard physiological laboratory and there has been discovered a group of remarkable alterations in the bodily economy associated with the emotions, which may reasonably be regarded as physiological adaptations and responses nicely adapted to the individual's welfare and preservation. The present volume recording these experiments and their interpretation may be regarded as the elaboration and outgrowth of the author's earlier period of researches on the motor activities and alimentary canal, which appeared in his important volume on "The Mechanical Factors of Digestion," in the series of International Medical Monographs, which was reviewed in the issue of the JOURNAL for April 11, 1912 (vol. clxvi, p. 564). The present work deals not merely with the effect of the emotions on digestion, but with the general organization of the visceral nerves concerned with the emotions, the relation of adrenal secretion and of carbohydrate metabolism to the emotions, the utility of the bodily changes produced by pain, the energizing influence of emotional excitement, the nature of hunger and the interrelation of the emotions. Of particular contemporary interest is the final chapter on alternative satisfactions for the fighting emotions, in which the author recognizes the fighting instinct as fundamental in mankind, and speculates on the possibility of the substitution for it, or rather, to employ the Freudian phrase, its sublimation into some form of the athletic instinct, which should afford a safe outlet for physical energy and gratification of the desire for conflict.

Each chapter closes with a brief bibliography on the subject which it considers and at the conclusion of the volume is a list of 20 published researches from the physiological laboratory in Harvard University on which the present account is based. Like its predecessor, this volume of Dr. Cannon's is to be regarded as deserving the highest praise as a valuable, original experimental contribution to the knowledge of the physiology of the emotions.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, JULY 22, 1915

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*
GEORGE G. SMITH, M.D., *Assistant Editor.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries beyond the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

THE RETIREMENT OF HEALTH COMMISSIONER GOLDWATER.

THE announcement that Dr. S. S. Goldwater is shortly to relinquish his position as head of the health department of New York has been received with profound regret, not only in that city, but wherever his admirable work in that capacity has become known and appreciated by those interested in sanitary science and the promotion of public health. When Dr. Goldwater accepted the commissionership it was with the understanding that the arrangement was to be temporary; and in response to urgent request, he has, in fact, remained in office for a considerably longer period than he originally anticipated. He is desirous to resume, in accordance with previous agreement, the post of superintendent of Mount Sinai Hospital, and the authorities of that institution are unwilling that this should be further delayed, especially

in view of the fact that the already very extensive buildings and work of the hospital are about to be materially enlarged, and in connection with this his services and advice are particularly required.

Under Dr. Goldwater's administration the progress made by the Department of Health has been remarkable, and many of the notable advances made have been referred to from time to time in the JOURNAL. Especially was comment made on the new sanitary code which, after the most elaborate preparation, both in the way of revision and providing many additional sections enlarging the department's field of operations, went into effect on January first.

Without further reference to what was accomplished in 1914, attention may be called to a report recently made by the commissioner to Mayor Mitchel, in which are recorded the many activities of the department in new directions during the present year. Among the noteworthy matters mentioned are the following: In addition to the new division of industrial hygiene another new division has been created, that of statistical research, and the effort will be made to utilize the work of this in such a way that other bureaus of the department will be guided in their own work by its findings. The department has advocated a higher standard of qualification for medical licensure, proposing that the present law should be so amended that, as is now the case in Pennsylvania and New Jersey, every graduate in medicine shall be required, before obtaining a license to practise, to have a training of not less than one year's duration in hospital or clinical work. In the meantime the department, having committed itself to such a standard, has requested the Municipal Civil Service Commission hereafter to admit no candidate to examination for appointment as medical inspector in the department who cannot show to his credit a year of clinical training. Post-graduate instruction in contagious diseases, including both clinical and bacteriological examinations, has been successfully organized at the Willard Parker Hospital. A special clinic of instruction has been established, under the auspices of the bureau of preventable diseases, to which all applicants for appointment to volunteer service in the tuberculosis clinics will hereafter be assigned for courses of instruction in physical diagnosis and for the study of branch-office and clinic routine. The division of efficiency and research has under way a careful

analytical study of the policies and especially the business methods of the bureau of laboratories. The Medical Societies of the Counties of New York and Kings, respectively, have been invited to cooperate with the department in the investigation of the work of the diagnostic laboratory, the efficiency of which is of such vital interest to the whole body of physicians in the city. A committee has been organized to formulate a plan for the establishment of a department training school for medical inspectors employed in the bureau of child hygiene. In collaboration with the Department of Education, there has been started, under the editorial management of the bureau of public health education, a publication entitled "School Health News," which is designed in part for the instruction of school teachers in matters of hygiene, and in part to stimulate cooperation between the school physicians and nurses on the one hand, and school principals and teachers on the other. The bureau of public health education has also undertaken, in cooperation with various neighborhood associations, the distribution of health leaflets in the form of "Neighborhood Chronicles," the first page of which gives the local news of a particular district, while other pages are devoted to general health notes. Special instructions have been issued to department employees to cooperate with the Tenement House Department in carrying out the law prohibiting the overcrowding of tenements. Recognizing the fact that office workers are being subjected more and more to conditions of employment which are injurious to health, the department has undertaken to investigate existing conditions, and, if necessary, will formulate a program for their amelioration. An investigation of a number of commercial laundries having shown that in the prevailing laundry methods neither the height of the temperature nor the duration of the application of the cleansing solution is sufficient to destroy completely all pathogenic organisms, the department has issued regulations for the control of laundries. A series of prosecutions has been begun for violation of the section of the sanitary code which prohibits the false labeling of medicinal preparations. This includes "any statement, design or device regarding the drug or its ingredients, or regarding its or their action on diseased conditions, which statement, design or device shall be false or misleading in any particular." The department has initiated a movement

for the prevention of street fatalities due to the operation of automobiles by incompetents. An educational lunch room has been opened in the department building. While the primary object is to provide a wholesome lunch for employees at cost price, an effort will be made to promote a knowledge of food and nutrition among the patrons of the lunch room and the public generally. As the abuse of alcohol constitutes an important public health question, a committee has been organized to outline a definite program of educational work among all classes against intemperance.

THE REALITY OF PSYCHOGENETIC AFFECTIONS: THE TRAUMATIC NEUROSES.

We should not forget that when we say psychic factor or psychogenetic induction of disease, we really do not mean anything more than a physiological process, for as a matter of fact, in any psychic reaction an actual change takes place in the energy output of the body, and we only state it in psychologic terms for brevity and convenience. Pavlov, Cannon and Crile have shown very conclusively the physical concomitants of some of the psychic reactions. Clinical experience has shown that psychic stimuli may cause intense reactions in the difference of the heart beat, extra secretions of various organs and alterations of the metabolism. These are all physical results of psychologic stimuli; so, after all, we are only dealing with medical, physiological facts when we talk about psychological or psychogenetic reactions.

The traumatic neurosis is purely psychic and can be dealt with psychologically only. (*Journal Abnormal Psychology*, 1910, June.) Its pathogenesis is derived from a false notion of the patient, which induces depressing emotions that disturb both bodily health and life relations. A clear illustration of the mechanism is that of the "conditioning" of the gastric reflex of dogs by psychological stimuli, whether these are pleasurable or painful. The removal of the extraneous suggestion would remedy any "neurosis" but for the fact that memory maintains its action; so that the mental content must be modified at its foundation, and this requires considerable analysis of the patient's trends. Hence the complete failure of such naive procedures as re-

assurance and suggestion. (*New York Medical Journal*, January, 1915.) Law suits and malingerings, so often interwoven with these cases, have created misunderstandings. But indemnity is not necessarily curative even of the malingerer. A case which lasted seven years after receiving heavy damages is an instance in Washington. (*American Journal Medical Sciences*, December, 1914.)

In the complicated case, proper psychological reconstruction, made possible by clear analysis, inevitably cures, as the mechanism of neurotic disturbances after accidents differs in no way from that which we find when there has been no accident at all. Furthermore, its nature is not of a complexity beyond the understanding of a layman; so that its principles can readily be grasped when presented in court by an expert witness who really understands them. (*New Orleans Medical Journal*, May, 1915.)

The object of treatment is not merely to sidetrack an unpleasant thought or emotion, but to re-educate the patient's tendencies in a fruitful direction which will preclude reactions of a disquieting or hurtful kind. The process can be most satisfactorily accomplished only when the practitioner has analyzed the psychic factors which enter into the disturbance. He does this in order to have an understanding of the mental processes with which he will have to deal in reconstructing the patient's reactions to the surroundings which have initiated or are maintaining his psychosis. ("Hysteria and Its Modern Treatment," *J. A. M. A.*, December, 1912.)

The procedure may be very complex, but in principle it does not differ from the very simple conditioning, reconditioning and deconditioning of autonomic reflexes practiced by Pavlov upon dogs in his experiments upon the functions of the digestive glands.

The principle is one of associating with useful activities, which very often means social relationships, the pleasurable feelings for which the patient has substituted some distressing emotion. When this is accomplished there ensues the spontaneous disappearance of the disagreeable feelings which are at the root of the disorder, thanks to a power of storing up impressions in the human cortex in the form of ideas, the constant activation of which may thus interfere with proper social adaptation through their "association" into a painful complex. ("Occupation Cramp," etc., *J. of Neurol. u. Psych.*, 1912, Bd. 19, etc.)

MIXED INFECTION IN TUBERCULOSIS.

THE specific character of tubercular infection should not give the impression that the tubercle bacillus is the sole organism playing a part in or influencing the course of this disease. Just as tuberculosis may be accompanied by or complicated with other diseases, which add to the burden that the body must overcome, and which so unfavorably influence the course of the dominant disease, just so may there be and are there frequently associated with the tubercle bacillus other organisms, which, though they are not causative of distinct disease entities, add materially to the severity, rapidity and the character of the disease. In the rapid fulminant type of pulmonary tuberculosis, in the so-called galloping consumption, where there is such rapid loss of weight, large variations and remissions in temperature, drenching sweats—very much as in pyemic conditions,—with marked destruction of tissue, there is the simultaneous action of other and commonly pus-forming organisms. This is particularly understood in consolidation and cavity formation, which, while they may be caused entirely through the action of the tubercle bacillus, are more likely the eventualities following mixed infection with other organisms—for it is here that such organisms are so frequently found.

The tubercle bacillus itself is culturally intractable—is slow growing, difficult to grow, delicate and selective of the media in which it will grow—and when acting alone in the tissues behaves in like manner. It is not properly a pyrogenic organism. The pus in the so-called cold abscesses in tubercular conditions is usually sterile—is not pus at all, but mixed debris from the disintegration of tissues in these conditions. And there is a positive danger in interfering with such infections for fear of converting these sterile tubercular abscesses into pyogenic abscesses, with serious effect to the patient.

In uncomplicated tubercular infection there is a tendency to subnormal temperature, and the afternoon rise of temperature is not a universal feature in pulmonary tuberculosis. The afebrile, sweatless and slowly progressing types of this disease are cases of pure infection. Except in the acute miliary form, tuberculosis is a local lesion and not a bacteriemia or septicemia and, therefore, except in conjunction with a mixed infection, leucopenia is usually the rule. Leucocytosis is, however, a constant accompaniment of

cavity formation, so much so that the continued absence of leucocytosis is considered good evidence of the absence of cavity in cases where the physical signs seem to point, but uncertainly, to that condition. The leucocytosis in pulmonary tuberculosis is usually polymorphonuclear.

The organisms most frequently found in mixed tubercular infections are the *streptococcus pyogenes*, the *staphylococcus pyogenes aureus*, the *diplococcus pneumoniae*, the *pneumobacillus*, and allied capsulated organisms. While the tubercle bacillus will not flourish culturally in symbiosis with other organisms, it does seem that symbiosis within the body favors rapid destruction of tissue, cavity formations, variations in temperature, sweats, rapid loss of weight and the induction of leucocytosis. In this connection the examination of the sputum has an added value besides merely as diagnostic of the specific presence of the tubercle bacillus, in the determination of prognosis, since an infection solely with tubercle bacilli as evidenced on microscopic examination is of good prognostic significance.

In the treatment of tuberculosis the dust-free, dry climate, away from the centres of population, with their congestive conditions and foci of infections, is as much a factor in anticipating mixed infections in individuals whose vitality is already sufficiently low and peculiarly susceptible to all infections, as it is in merely creating conditions unfavorable for the growth of the tubercle bacillus.

THE DIFFERENTIATION OF BODY TYPES.

In another column of this issue of the JOURNAL we publish a communication calling attention to a paragraph in which Mr. Galsworthy has recently denoted the differentiation between the two body types which Dr. Goldthwait and Dr. Bryant in the columns of this JOURNAL have recently described as herbivorous and carnivorous. It is of interest in this connection also to call attention to an article by Dr. McEvoy on "Stomach Diseases from a Medical Standpoint," which appeared in the issue of the JOURNAL for November 3, 1910, in which the differentiation of body types and the clinical importance of this differentiation is pointed out. In 1914 also Dr.

McEvoy presented before the Norfolk District Medical Society a continuation and further elaboration of his method of distinguishing these body types, which he classes as broad, normal and narrow. As was pointed out in our editorial of June 17, this recognition of differing physical types in man is not a new observation, but the understanding of its meaning has been a relatively recent development. In this comprehension the work of Goldthwait and Bryant seems to have been of particularly illuminating value and this value is increased by the citation of the interesting parallel comment by Mr. Galsworthy who, as a layman, has noted the significance of the physical phenomena of body types and their differentiation.

THE USE OF IODINE IN SURGICAL FIRST AID.

ONE of the interesting advances in surgical first aid which has come into prominence in conjunction with the present European War has been the use of iodine for the immediate sterilization of wounds. For this purpose a solution of iodine is put up in 3½% in glass ampoules, each containing about 2 c.c. and provided with a rubber bulb for expression of the contents. These ampoules can readily be carried by each soldier as part of his equipment, and the men are instructed how to break off the glass tip of the ampoule and inject the contents into the wound or spread it over the injured surface. Preliminary statistics from the European War hospitals indicate that wounds treated in this way with the immediate subsequent application of a sterile dressing show a much lower percentage of serious infection than wounds treated by sterile dressing without iodine. These first aid ampoules are equally applicable in times of peace to the manifold open traumata of civil and industrial life.

CHOLERA IN AUSTRIA.—Report from Zurich, Switzerland, on July 16, states that the Austrian ministry of the interior has officially announced that on July 12 there were in the Austro-Hungarian Empire 809 cases of Asiatic cholera, as against only 77 cases on July 8. The rapid increase of this disease has occurred chiefly among prisoners of war in Galicia.

A NEW MEDICAL SOCIETY.

IN another column of this issue of the JOURNAL we are glad to note the establishment in Boston of a new medical society, the "New England Society of Dermatology and Syphilis." The multiplication of medical societies leads sometimes to confusion and duplication of work, but in the present instance there seems a definite and important field for this latest organization. The clinical facilities for the study and advancement of dermatology and syphilis in the larger cities of New England are of a value and extent second only to those of the greatest metropolitan centers. It is felt that such a society as that just established will serve not only to coordinate the work of those already engaged in this field but to stimulate the interest of general practitioners in a due attention to this important special branch of medicine. In behalf of the profession the JOURNAL is glad to extend cordial greetings and good wishes to this latest medical society.

 MEDICAL NOTES.

MEASLES ON THE DECREASE IN NEW YORK.—According to figures compiled by the Bureau of Records of the Department of Health, the outbreak of measles which has prevailed in New York City for the past few weeks has passed its height and is now declining. The decline is clearly reflected in the death-rate, 11.02 per one thousand of population, as compared with 11.24 for the corresponding week of 1914. This difference of .22 points in the weekly rate means an increase of 23 deaths. The death rate of the first 28 weeks of 1915 is lower than the same rate for the corresponding period of 1914, when it was 14.51. Measles and scarlet fever were the only epidemic diseases to show increase over the corresponding week of last year. The others all showed a gratifying decline. Organic heart disease showed an increase of 22 deaths, but when considered in conjunction with chronic Bright's disease, the increase amounted to but one death. There was an increase of 22 deaths from pulmonary tuberculosis last week, as compared to the corresponding week of last year. This increase is undoubtedly to be attributed to the changeable weather that prevailed, which hastened the end of those sufferers from this disease whose life was on the ebb.

INCREASE IN FOURTH OF JULY ACCIDENTS.—According to an investigation just completed by the Department of Health no fatal casualties attended the celebration of the 4th of July in New

York. There was, however, an alarming increase in the number of accidents that resulted from the misdirected enthusiasm of the younger celebrants. Inquiry at the larger hospitals of the city, particularly those having an ambulance and an out-door service, elicited the information that the number of 4th of July accidents showed an increase of more than 100% over similar accidents in 1914, and that most of the wounds had been caused by the use of blank cartridges. Post-mortem inquiry will not remedy that which has already happened, but the results of such inquiry should be used next year to re-stimulate public interest in, and support for, a safe and sane Fourth.

BEQUEST TO UNIVERSITY OF PENNSYLVANIA.—The will of the late Samuel Dickson of Philadelphia establishes a trust fund of \$100,000, one-half of the proceeds of which is to be devoted to the William Cutler Clinical Laboratory of Medicine.

AMALGAMATION OF TWO MEDICAL COLLEGES.—It is announced that the Hahnemann Medical College of San Francisco has offered to convey its property to the University of California and to cease giving separate instruction, on condition that two professorships, in homeopathic materia medica and therapeutics be maintained at the University of California Medical School. The instruction in these subjects is to be elective.

EUGENIC MARRIAGES IN WISCONSIN.—Report from Madison, Wis., on July 10, states that since the so-called eugenic marriage law went into effect in that state the total number of marriages has declined from 21,052 in 1913 to 17,245 in 1914.

THREE OUTBREAKS OF SMALLPOX.—The weekly report of the United States Public Health Service for July 2 notes that during the week ended June 12, 1915, five cases of virulent smallpox and two deaths were reported at Brownsville, Texas, and seven cases and two deaths at New Orleans, La. During the week ended June 26, two new cases of smallpox were reported at New Bedford, Mass., making a total of twenty cases, of which nine were fatal.

WOUNDS INFECTED BY PHOSPHORUS.—It is reported in the publications of the Société de Biologie by Victor Henri that wounds received from German shrapnel are often seriously infected by phosphorus. The balls of shrapnel are covered by a violet red powder composed of over ninety per cent. of phosphorus. When a soldier is hit by a bursting ball the powder is either carried directly into the wound or is ignited and oxides of phosphorus or white phosphorus enter the wounds, in which latter case death is likely to ensue shortly. The phosphorus coming in contact with the tissues disposes them to morti-

fication and provides abundant opportunity for thriving bacteria.

A PUBLICATION ON PREVENTION OF BLINDNESS.—The National Committee for the Prevention of Blindness has recently issued a pamphlet prepared by the Ohio Commission for the Blind called "Common Causes of Blindness in Children," in which are clearly set forth various common eye diseases and valuable advice and suggestions as to the proper protection of eyesight. The booklet is illustrated with striking pictures and its simply stated facts and rules are well calculated to impress themselves on those who, by their ignorance or carelessness, might be the cause of unnecessary blindness in themselves or in those dependent on them.

PREVALENCE OF MENINGITIS, MALARIA, PELLAGRA, POLIOMYELITIS, SMALLPOX AND TYPHOID.—The weekly report of the United States Public Health Service for July 2 notes that during the month of May, 1915, there were reported eighteen cases of cerebrospinal meningitis in Virginia, twelve in Ohio and five in Mississippi. During the same period there were reported in Mississippi 7092 cases of malaria, 2187 of pellagra and 254 of typhoid fever. In Virginia there were also eighteen cases of poliomyelitis, 108 cases of smallpox and 149 cases of typhoid. In Kansas there were 301 cases of smallpox and 36 of typhoid, in Ohio 305 of smallpox and 207 of typhoid, and in Indiana 487 of smallpox and 61 of typhoid.

TYPHOID FEVER IN THE UNITED STATES.—A recent bulletin of the United States Public Health Service calls timely attention to the discreditable fact that the proportion of the prevalence of typhoid fever in this country is from two to five times as great as the rate in leading European nations. During the past year there were approximately 400,000 cases of typhoid fever in the United States, with 30,000 deaths. The bulletin continues in part as follows:—

"In many American cities there has occurred within the last twenty years a considerable reduction of typhoid fever. Due in a large part to improved sanitary conditions in the cities, the typhoid rate for some entire states has shown a material decrease. For the country as a whole, according to the available figures, the rate has been reduced about 50% in the last forty years. But the present rate is about the same as that which prevailed in some of the other advanced nations of the world thirty years ago. In other words, the United States is a generation behind the times in respect to the reduction of its typhoid rate. In recent years a specific method for increasing individual resistance to typhoid germs has been employed. This is known as anti-typhoid inoculation or 'vaccination.' It is pointed out, however, that the protection given by anti-typhoid inoculation is relative, not abso-

lute, and that such inoculation is not to be regarded as a substitute for sanitation."

NEW YORK ASSOCIATION FOR IMPROVING THE CONDITION OF THE POOR.—The Department of Social Welfare of the New York Association for Improving the Condition of the Poor was given, in April, 1913, by Mrs. Elizabeth Milbank Anderson, a memorial fund to be used "in fostering preventive and constructive social measures as distinguished from relief measures." A recently published report records the various uses to which the fund was put. The Bureau of Welfare of School Children, in coöperation with the Health Department, took up the work of medical inspection of school children, dental clinics, and the sanitary survey of school buildings. It had been estimated that of the children examined, 69.7% were reported in need of treatment, and of that number 23.9% had received adequate attendance. In connection with the New York School Lunch Committee, it supplied approximately one and one-half million portions of food to school children, and has taken steps to maintain lunch rooms in high schools where lunches may be furnished the pupils at actual cost. In coöperation with the Bureau of Public Health Education of the Department of Health a Bureau of Food Supply has been established and a Food Supply Store, which is operated on strictly business principles, is on an entirely self-supporting basis. The Bureau of Public Health and Hygiene made a sanitary survey of the various public bathing pools in Manhattan, and a campaign to increase the attendance at the Milbank Memorial Bath resulted in an increase of 2896 bathers in one month over a similar period of the previous year.

Completely financed from Department of Social Welfare funds, the activities of the Ventilation Commission are under the direction of Professor C. E. Winslow, the permanent chairman. The commission is now completing the second year of its investigation by means of which it is attempting to determine, through the experimentation plant established at City College and the specially equipped public school in the Bronx, the real importance of the chemical theories of air vitiation, the effects of temperature and humidity upon physiological reactions, working conditions, appetite, etc. A similar series of measurements is being conducted regarding the effect of dry, cold and re-circulated air, of various methods of air distribution in a room, types of window ventilation, etc. As a result of this investigation it is expected that adequate and reliable standards of proper ventilation will be determined upon, and practical, yet scientific, methods of ventilation for schoolroom, workshop and home recommended.

EUROPEAN WAR NOTES.—There is increasing evidence of the shortage of medical men in

Great Britain, not so much in the army as at home, where the remaining practitioners are greatly overworked attending to the patients of their colleagues at the front. In Germany, on the other hand, there appears to be no such shortage since the recent increase in the number of medical men in that country is considerably higher. In 1886 there were 26,452 physicians in Great Britain and only 16,292 in Germany, whereas in 1910 the number of physicians in Germany had increased 100% and that in Great Britain only 33%.

In its issue of July 3 the *Lancet* chronicles, as follows, the arrival in London of the surgical unit from the University of Chicago:—

"There arrived in England from the United States last week a complete unit known as the Chicago unit, whose services have been accepted by the War Office as the full medical and nursing establishment for a general hospital of 1040 beds. The unit consists of 32 medical men and the nursing staff of 75, including the matron. The medical staff includes, besides physicians and surgeons, specialists in eye, nose, throat and ear, and oral surgery, a radiographer, and a pathologist. The medical men of this unit have been carefully selected out of several hundreds of applicants, the senior officers being all men of established position, while the nurses are all fully trained and have served in large general hospitals in the United States. The junior members of the Chicago unit were temporarily distributed among various general military hospitals in London on the day of their arrival, pending the departure of the unit to its allotted sphere of action. It is planned to keep the hospital corps intact for at least six months, its subsequent permanency being assured by the large waiting list of American medical men and nurses ready to fill up the places of those who may then wish to retire. All members of the unit have been inoculated, in addition to the customary smallpox and typhoid vaccination, with the new Plötz vaccine against typhus fever, supplied from the Mount Sinai Hospital, New York."

The Victoria Cross has recently been awarded for distinguished gallantry to Dr. Francis Alexander Caron Seringer, surgeon-captain of the 14th Battalion, Royal Montreal Regiment, Canadian Army medical service. In the headquarters' report recommending Dr. Seringer for this honor, his conduct was described as follows:—

"On the afternoon of April 25, 1915, in the neighborhood of Ypres, when in charge of an advanced dressing station in some farm buildings, which were being heavily shelled by the enemy, he directed under heavy fire the removal of the wounded, and he himself carried a severely wounded officer out of a stable in search of a place of greater safety. When he was unable alone to carry this officer further, he remained with him under fire till help could be obtained. During the very heavy fighting between April

22 and 25, Captain Seringer displayed continuously day and night the greatest devotion to his duty among the wounded at the front."

On July 17 the total of the principal New England relief funds for the European War reached the following amounts:—

Belgian Fund	\$265,114.25
Red Cross Fund	136,998.60
Jewish Fund	65,225.86
Polish Fund	48,728.01
British Imperial Fund	31,201.17

The principal state contributions to St. George's Fund are as follows:—

Massachusetts, \$10,517.69; Pennsylvania, \$4,830.41; New Jersey, \$4,032; Connecticut, \$3,800; New York, \$3,173.57; Illinois, \$3,139.89; Pacific Coast, \$2,148.92; Michigan, \$1,865.75; Ohio \$1,373.32; Rhode Island, \$1,200.45.
--

BOSTON AND NEW ENGLAND.

NEW ENGLAND SOCIETY OF DERMATOLOGY AND SYPHILIS.—On May 6, 1915, at a meeting of physicians from various New England cities, held at the Massachusetts General Hospital, there was formed the New England Society of Dermatology and Syphilis. The following officers were elected: Dr. Abner Post, president; Dr. Townsend W. Thorndike, vice-president; Dr. Charles J. White, secretary. Boston was chosen as the meeting place of the society. It is proposed to hold four meetings a year between the months of October and May at some hospital, and to make the clinical exhibition and demonstration of cases a prominent feature of each meeting. The success of the clinical session has already been assured by the heads of the departments for dermatology and syphilis in several hospitals who have promised the use of the combined material of their several clinics. The declared object of the society is to promote the interests of dermatology and syphilography in New England. The meeting recognized the fact that, while the number of specialists has steadily grown larger, the general medical public has also given many signs of increasing interest in these subjects. It was felt, therefore, that the society would best fulfil its purpose by including both classes in its membership, and, accordingly, has opened its membership to all reputable physicians practising in New England.

On these foundations the society asks the support and coöperation of the profession at large. Applications for membership may be sent to Dr. Charles J. White, 259 Marlborough Street, Boston.

THE BOSTON FLOATING HOSPITAL.—In the JOURNAL of July 8 mention was made of the staff of the Boston Floating Hospital for this season. The name of Dr. Elmer W. Barron is now added as visiting physician in the day patients' department of the hospital.

The trustees desire all persons interested in the institution to have opportunity to inspect the hospital and see how its work is conducted.

The boat returns daily (including Sundays) at 4.30 in the afternoon, to North End Park Pier, Commercial Street, where visitors are welcome until 7 p.m.

BACKWARD CHILDREN IN BOSTON SCHOOLS.—In September there will be opened in Boston, under the direction of Miss Ada M. Fitts, a school for backward children, with an enrollment of about 750 pupils. Examination of these pupils, made by the medical department of the schools, showed that in very few instances was mental deficiency the cause of the backwardness, but often lack of sufficient food, and in many cases insufficient sleep and defective teeth were contributing causes in keeping pupils below normal. It is expected that by regulating habits of living to hygienic principles and with proper instruction, the majority of pupils will later be enabled to enter their regular classes.

BOSTON INSTRUCTIVE DISTRICT NURSING ASSOCIATION.—The report of the Boston Instructive District Nursing Association for June, 1915, states that during that month 10,777 visits were made by nurses. There were 928 new cases. One patient, during the past five years, has received 990 visits and is now dead.

MILK AND BABY HYGIENE ASSOCIATION.—The semi-annual report of the Milk and Baby Hygiene Association shows a steadily growing increase in the number of babies, both sick and well, that the Association has under its supervision. The number cared for during the first six months of this year was 3097, an increase of 18% over the first half of 1914. The attendance at 233 "well baby clinics" was 11,398, an increase of 47% over 1914. Nurses made 23,965 home visits and four extra nurses are doing summer work. Contributions to the work of the association may be sent to F. Abbot Goodhue, treasurer, 26 Bennet Street, Boston.

The following named persons were elected members of the medical advisory committee of the association: Richard M. Smith, M.D., chairman; Henry I. Bowditch, M.D., Walter B. Cannon, M.D., Charles Hunter Dunn, M.D., Arthur A. Howard, M.D., Maynard Ladd, M.D., Ralph C. Larrabee, M.D., John Lovett Morse, M.D., Milton J. Rosenau, M.D., Fritz B. Talbot, M.D., and Charles W. Townsend, M.D.

HOSPITAL BEQUESTS.—The will of the late Mr. Frederick S. Pearson of Great Barrington, Mass., who died at the sinking of the *Lusitania* in May, was filed on July 12 for probate at Pittsfield, Mass. It contains bequests of \$50,000 each to the Lowell (Mass.) General Hospital and to the House of Mercy Hospital in Pittsfield, Mass.

PREVENTION OF RABIES IN BOSTON.—In last week's issue of the JOURNAL we noted the prevalence of rabies in several towns of this Commonwealth and the local measures undertaken for its

suppression. On July 12 the Boston City Council passed an order requiring that all dogs within the city limits be muzzled or kept under restraint for the next ninety days.

COMPLICATION IN DENTAL REGISTRATION.—In the issue of the JOURNAL for April 15 we commented editorially on the dental registration bill then pending before the Massachusetts General Court; and in the issue of June 10 we noted its final passage and its approval by the Governor. The new law went into effect on May 31, and as a result there has arisen a peculiarly complicated situation.

The act created a new board, to be known as the Board of Dental Examiners and provided that it should consist of the then members of the old Board of Registration in Dentistry.

The old board began on May 24 a series of examinations which were not completed until June 1. The examinations were conducted under the old law and did not include a demonstration in prosthetic dentistry, as is required by the new law.

This examination was taken by 201 candidates, of whom 115 passed. The question now arises, however, whether even the successful candidates can legally be registered as dentists in this Commonwealth, since their examination did not include the new requirement provided in the bill. Being in doubt as to their rights to issue certificates under these circumstances, the members of the Board referred the matter to the attorney-general for his opinion and decision. The following is the communication as submitted to him:—

"The Board of Dental Examiners of this Commonwealth respectfully request your opinion on section 7, chapter 301, General Acts (an act relative to the practice of dentistry).

"The June meeting of said board for the examination of candidates having been advertised in March and April to be held on June 1, 2 and 3, 1915, under Chapter 137 of the Acts of 1887, and amendments thereto, did not include demonstrations in prosthetic dentistry, as provided for in the law approved by the Governor May 31, 1915.

"The Board of Dental Examiners desires to know if a certificate of fitness to practice dentistry can be issued to those who passed successfully the examination. What rights, if any, have those who failed in their examination?"

In reply to these queries the attorney-general rendered the following decision:—

"In my opinion your first question must be answered in the negative, since the right of the board to issue certificates under the provisions of the act is based upon the prerequisite that candidates have been examined in the manner prescribed by the statute.

"As to your second inquiry, I am of the opinion that those who failed in the examination which was taking place at the time of the passage of the act have no rights as against the

Commonwealth, other than to have the opportunity of being examined upon the subjects required by the provisions of the statute. If they are now examined in relation to their knowledge and capacity in prosthetic dentistry, and the board, taking into consideration their capacity in relation to this subject, should be still of the opinion that they are not qualified to practise dentistry in this Commonwealth, I am of opinion that they can have no complaint."

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending July 13, 1915. Diphtheria, 58, of which 12 were non-residents; scarlatina, 39, of which 7 were non-residents; measles, 97; tuberculosis, 65, of which 1 was non-resident. The death rate of the reported deaths for the week was 13.27.

Obituary

FREDERICK HOWARD MARSH, M.A.,
M.C., Sc.D. (CANTAB.), F.R.C.S. (ENG.)

DR. FREDERICK HOWARD MARSH of Cambridge, England, who died on June 24 at Downing Lodge, was born at Homersfield, Suffolk, in 1839. He entered the medical school of St. Bartholomew's Hospital, London, in 1858, and in 1861 qualified as a member of the Royal College of Surgeons of England, of which he became a Fellow in 1866. During the decade following his medical studies at St. Bartholomew's he served as demonstrator of anatomy in the medical school and held other minor appointments. Finally in 1873 he became assistant surgeon to St. Bartholomew's Hospital and shortly thereafter surgeon to the Children's Hospital on Great Ormond Street. In these positions Dr. Marsh served during the busy years of his early professional life. In 1892 he became full surgeon at St. Bartholomew's and in 1904 retired as consulting surgeon to that institution and to the Ormond Street Hospital. Throughout this period he was also lecturer in anatomy and in surgery at the medical school. He early acquired a reputation as a consulting surgeon, especially in diseases of the joints, and this reputation was soundly built upon his profound knowledge as an anatomist and pathologist. In 1895, as a result of his extensive clinical experience he published his book on "Diseases of the Joints and Spine," which has become a standard work on orthopedics. He also edited the clinical essays and lectures of Sir James Paget, his predecessor at St. Bartholomew's and likewise a native of Suffolk. He was a frequent contributor to the *Lancet* and to other medical publications. In 1902 Dr. Marsh delivered the Bradshaw Lecture before the Royal College of Surgeons on "Infective Arthritis."

In 1903, just prior to his retirement from active hospital work, Dr. Marsh was appointed regius professor of surgery at the University of Cambridge, a position which had been in abeyance since the death of Sir George Murray Humphrey. In this new position he manifested the same zeal and enthusiasm that he had shown as a teacher in London and he was enabled to continue his clinical interest at Addenbrooke's Hospital in Cambridge. His popularity was evidenced by his election in 1907 to the mastership of Downing College. These two Cambridge offices he continued to hold at the time of his death. He continued also prominent and successful as a consultant in both Cambridge and London, and in recent years had served as honorary colonel in the East Anglian division of the territorial force of the Royal Army Medical Corps. As a teacher he was breezy, unconventional, genial, courteous and good natured and had a remarkable facility for simple and clear exposition.

Professor Marsh was vice-president of the Royal College of Surgeons of England in 1898, an honorary Fellow of the Royal Academy of Medicine in Ireland, a corresponding member of the Orthopedic Society of New York and a member and former president of the Clinical Society of London. He is survived by his widow, one daughter and one son.

Miscellany.

A JUDICIAL OPINION ON CHIROPRACTIC.

IN the issue of the JOURNAL for June 10 we commented editorially on a recent legal decision in the case of the New England College of Chiropractic, Inc., and cited a portion of the judge's opinion. The brief for the Commonwealth in this case argued that the statutes are constitutional and that the jury were warranted in finding that the defendant practised medicine. Upon this basis it was contended that the exceptions taken by the defendant from the superior court should be over-ruled. The complete text of the judge's opinion upon this case is as follows and presents several points of especial interest to members of the regular profession.

"The defendant has been found guilty of violation of Revised Laws, Chap. 76, Sect. 8, in that he practised medicine without being lawfully authorized. He defends on the ground that he is a chiropractor and that his acts do not constitute a violation of the statutes. The evidence tended to show that he kept an office in Boston, indicated by a sign on which was his name, followed by the word chiropractor; that he practised for pay; that he said that the basis of

chiropractic is the the adjustment of the vertebrae of the spine; that the vertebrae when not in their normal positions press upon the nerves of the spine; that the malposition of these vertebrae was the cause of abnormality and that an adjustment of these vertebrae to their normal positions would remove the pressure at the spine; that he said that he did not cure, that he simply adjusted. He testified that "chiropractic is the specific science that removes pressure upon the nerves by adjustment of spinal vertebrae; there are no instruments used, it is done by the hand only." The treatment pursued by the defendant was to have those who resorted to him go into an inner room and remove their outer garments until they were stripped to the waist. The patient then took a sitting position. The defendant examined down the spine, beginning at the top, by feeling with his fingers to see whether each vertebra was in its proper position. The method to discover whether a vertebra was out of position was by making a gliding move of the three middle fingers of the right hand, which constituted the process of "palpation," whereby one vertebra was compared with another. As a result of this "analysis" the defendant was able to tell whether vertebrae were out of alignment or out of their normal position.

In making "adjustments" the patient was placed on a low table with face downward, and the vertebra which was out of condition was given a quick thrust or push by the hands of the defendant. The acts performed by the defendant constitute, first, an examination of the vertebrae of the spinal column and a determination whether they are in a normal position; and, second, a manipulation of such of the vertebrae as are found to be out of position, so that they will become regular and correct with reference to each other. Although the defendant did not prescribe medicine, and testified that he paid no attention to the patient's description of symptoms of disease, yet it is obvious that his purpose was to treat the human body in order to make natural that which he found abnormal in the narrow field of his examination. The removal of pressure upon nerves is a means of relieving the ills flowing from that source. "Chiropractic" is defined as "A system of healing that treats disease by manipulation of the spinal column." (Webster's International Dict.) The plaintiff's manipulation was of a most important part of the body and related to a nerve center. It might have been found that it could have no other aim than a prevention of disease or relief from existing disarrangement of body functions. That which the defendant did and its manifest purpose might have been found to be practising medicine within the meaning of the statute. Medicine relates to the prevention, cure and alleviation of disease, the repair of injury, or treatment of abnormal or unusual states of the body and their restoration to a healthful condition. It includes a broad field. It is not con-

fined to the administering of medicinal substances or the use of surgical or other instruments. It comprehends "a knowledge not only of the functions of the various organs of the human body, but also the diseases to which these organs are subject, and the laws of health, and the modes of living which tend to avert or overcome disease, as well as the specific methods of treatment that are most effective in promoting cures." (Knowlton, C. J., in *Commonwealth v. Jewelle*, 199 Mass. 558, 560.) In order to practise medicine one need not cover the entire field of the science. If he devotes himself to a very restricted part of it he still may be found to practise medicine. It is matter of common knowledge that there has been great specialization in that profession in recent years. To that effect are the decisions: *Commonwealth v. Porn*, 196 Mass. 326. *People v. Gordon*, 194 Ill. 453. *Witty v. State*, 173 Ind. 404. *People v. Allcutt*, 117, App. Div. 546, affirmed in 189 N. Y. 517.

It is of no consequence that the defendant abstained from the use of the words diagnosis, treatment, or disease, in description of what he did, and employed the terms "analysis," "palpation," and "adjustment." The acts which he did and their manifest design are to be examined rather than the words used, in order to ascertain the true nature of the defendant's conduct. A physical examination of the vertebrae, a decision whether they are in normal position or not, and strong manual pressure upon them with the end of changing the position with reference to each other of those found to be irregular, and thereby relieving pressure upon nerves, may be found to have such relation to the cure or prevention of disease or the relief of pain as to constitute the practice of medicine. Numerous decisions upon kindred facts point in the same direction: *State v. Corwin*, 151 Iowa, 20. *Green v. Hodges*, 91 Kan., 658. *State v. Smith*, 233 Mo. 242. *Swarts v. Siverney*, 35 R. I., 1. *State v. Grenier*, 63 Wash. 46.

The judge stated to the jury, without objection or exception, that "the defendant did not claim that he came within any of the exceptions of Sect. 9 of Chap. 76, of the Revised Laws." Hence it is not open to the defendant now to contend that his practice rightly may be described as "cosmopathic method of healing," the final exception in Sect. 9. Even if this point had been saved, there is nothing in it. "Cosmopathic" is defined in the Standard Dictionary as "open to the access of super-normal knowledge or emotion supposedly from a pre-natural world." Without undertaking to decide what a "cosmopathic method of healing" may be, plainly it does not include the defendant's operations.

The statute as thus construed is constitutional. That was decided in *Commonwealth v. Porn*, 196 Mass. 326, and affirmed in *Commonwealth v. Jewelle*, 199 Mass. 558. A somewhat similar statute was upheld in *Hewitt v. Charier*, 16 Pick. 353. To the same effect in principle are

Dent v. West Virginia, 129 U. S. 114, and Collins v. Texas, 223 U. S. 288, and cases there cited. See also State v. Johnson, 84 Kan. 411. The protection of the public from those who undertake to treat or manipulate the human body without that degree of education, training and skill which the legislature has prescribed as necessary to the general safety of the people is within the police power of the state. This general purpose may be effectuated by requiring even of those who propose to confine their practice to a narrow specialty a much broader knowledge of the subject, provided such qualification is regarded by the legislature as necessary for the practice of any branch of medicine. The statute does not impair in any constitutional sense the liberty of the defendant. The protection of the public health is an object of such vital importance to the welfare of the state that any rational means to that end must be upheld. The defendant is placed in no worse position than others. The circumstances that Revised Laws, Chap. 76, Sect. 9, to an extent (see Com. v. Delon, 219 Mass. 217), exempts certain classes, such as osteopaths and pharmacists, and those practicing Christian Science, mind cure, massage and others, does not render the statute unreasonable as to the defendant nor deny to him the equal protection of the laws. Rational classification is within the power of the legislature. Its determination in this regard cannot be overthrown upon the facts disclosed on this record. Every constitutional aspect of the statute is so fully covered by the decisions above cited that further discussion would be superfluous.

Exceptions overruled.

THE PREVENTION OF INDUSTRIAL DISEASES.

THE Massachusetts State Board of Labor and Industries has recently sent to every practising physician in this Commonwealth the following circular letter calling attention to the regulation relative to industrial diseases:—

Boston, June 19, 1915.

Dear Doctor:

Your attention is respectfully called to the following regulation relative to industrial diseases in Massachusetts:—

Under authority of Section 6 of Chapter 813 of the Acts of 1913 the Joint State Board of Labor and Industries and Industrial Accident Board hereby requires that every physician treating a patient whom he believes to be suffering from poisoning from lead, brass, phosphorus, arsenic or mercury or their compounds, or wood alcohol, or from anthrax, or from compressed air illness, report within 48 hours to the State

Board of Labor and Industries, the information relating thereto called for by the reporting blanks issued by the said Board. Every such physician is hereby requested to make reports on the said blanks to the State Board of Labor and Industries of any patient whom he treats that is suffering from any other ailment or disease which the physician believes to have been contracted as a result of the nature, circumstances or conditions of the patient's employment. (Adopted Jan. 23, 1914.)

The Board believes that the first essential in the campaign against occupational diseases in this state is to secure definite data as to the number and the location of these diseases. The great, unnecessary wastage of human life and health occurring each year because of conditions directly or indirectly associated with occupational life is familiar to every physician. He sees daily in the consulting room, in the home and in the hospital, person after person whose working efficiency has been lessened or destroyed by accident or by unhygienic surroundings associated with many lines of employment. Nevertheless, when we try to analyze the various occupational diseases or ailments caused by or associated with specific employments by reason of the nature, circumstances or conditions of that employment, few or no reliable data upon which to build a conclusion are available. Without such a basis, little or no progress can be made in combating even the more prevalent of the occupational diseases. The medical profession alone can furnish the necessary facts for the basis of this most important branch of preventive medicine.

The State Board of Labor and Industries invites your coöperation and assistance in a study of the prevalence of occupational diseases in Massachusetts. To that end you are requested to fill out the enclosed data blank and return the same to this office at your earliest convenience.

All data and information furnished by you are to be considered *confidential* and if used publicly by this department will be free from any mark of identification.

Relying on your aid and coöperation in this most important survey, I have the honor to be,

Very truly yours,

THOMAS F. HARRINGTON, M.D.,

Medical Deputy Commissioner.

With the above communication was sent also a copy of the following circular letter which had been previously issued to the public press concerning the organization of an industrial hygiene corps.

Boston, June 15, 1915.

The State Board of Labor and Industries has inaugurated a state-wide organization of wage-earners into an industrial hygiene corps for the

purpose of giving to persons injured or taken ill upon the premises in the various lines of industry, intelligent first aid attention and at the same time establishing a system of medical reports from the various industries of the state. This undertaking is undoubtedly one of the most comprehensive and far-reaching organizations for bettering the health and reducing illnesses among wage-earners ever undertaken in any state in the country.

There are in Massachusetts more than 600,000 wage-earners in the various industries. Accidents and illnesses in one degree or another are occurring continually in shops, factories and industrial establishments. Much of the seriousness of these cases depends upon the kind of attention given to the person at the time of the accident or at the onset of an illness. Very often life itself depends upon the cool, intelligent action of a fellow worker present at the time. It is not always practical to have a doctor or a nurse on the premises,—although very many of the industries of the state are now maintaining such professional supervision over their employees,—nevertheless it is possible and feasible to have in each establishment and in every department of the establishment one or more persons sufficiently instructed and trained to render safe first aid care until the arrival of the physician, or, in the case of sudden illness, to prevent a delay in sending for medical assistance whenever a doctor is necessary.

There are innumerable occasions of simple accidents and illnesses which can be cared for at the time by persons who have been specially instructed. Too often these simple conditions are neglected or improperly treated, and, as a result, serious illness, incapacity and loss of wages result. It is said that more than 4% of the population of Massachusetts is on the sick list all the time from illnesses which are preventable.

The persons appointed as hygiene assistants, instructors or supervisors will be adequately instructed not only to render suitable temporary surgical and medical aid, but likewise instructed in the early signs and symptoms of the common affections and illnesses. These various assistants will also be in the best possible position to give to the medical department of the State Board of Labor and Industries a regular report on the illness or accidents occurring in various lines of industrial life and the consequent loss of time resulting from such illness. These data are not available anywhere today and are most essential in the fight against occupational diseases and accidents now being undertaken by the State Board of Labor and Industries. The persons selected to act as industrial hygiene assistants will be graded according to the conditions existing in the various mercantile and industrial establishments. The number and rank of the persons so selected will depend upon the number and kind of wage-earners being protected. At the head of each division, however, there will be a physician or other specially trained person or

chief to whom the assistants will be responsible. These chiefs will be in close touch with the Medical Deputy Commissioner of Labor, Dr. Thomas F. Harrington.

The Legislature has given to the State Board of Labor and Industries the authority to require all industrial concerns to keep and maintain free of expense to the employees a medical and surgical chest, containing plasters, bandages, absorbent cotton, gauze and all other necessary medicines, instruments and appliances for the treatment of persons injured or taken ill upon the premises. Also to require that suitable accommodations shall be provided for the treatment of persons injured or taken ill upon the premises. Many places of employment are now equipped with such a medicine chest, and in many establishments a physician, nurse, social worker, foreman or forewoman has been placed in charge of the supervision of the health of the employees.

In addition to this corps of health supervisors, the Medical Department of the State Militia is instructing a large number of its officers and privates each year on problems of personal hygiene, exercise, rest, sanitation, etc. These men are chiefly employed in the manufacturing and mercantile establishments. Adjutant-General Cole and Surgeon-General Frank P. Williams of the State Militia have both endorsed this plan of health supervision and have promised their coöperation in fitting the lectures and demonstrations given in the Militia to conditions likely to be met in the various industries of the state. In many localities the surgeons of the Militia, in addition to the physicians associated with the many industrial and mercantile establishments, will be requested to act as chiefs of the various divisions of industrial hygiene assistants. Lectures and demonstrations of a practical nature will be given by these various medical authorities upon the various dangers of industrial life as well as upon the prevention of occupational diseases. All the instruction will be of such a practical nature that it can be carried out not only in the shops, factories and industries of the state, but also in the homes of the wage-earners. Mr. Edwin Mulready, Commissioner of Labor and Industries, believes that this will give to Massachusetts an organization for bettering the health conditions among its people far in excess of that possessed by any other state in the country.

These two communications represent the inauguration of an important attempt to further the cause of preventive medicine among the industrial classes of this state and it is earnestly to be hoped that members of the profession, by filling in and forwarding the blank report form accompanying the former letter, may evidence their intelligent appreciation of the significance of this movement and their willing desire to co-operate in making it successful and thereby contributing to the benefit which it may be expected to produce in the welfare of the community.

Correspondence.

PARIS LETTER.

THE FRENCH SOLDIER OF 1915.

(From Our Special Correspondent.)

PARIS, JUNE 19, 1915.

Mr. Editor: At an ambulance that I visited the other day a soldier was brought into the operating room in a fearful state; his left foot had been shot off above the joint, he had a nasty wound of the abdomen, fortunately non-penetrating, and a piece of shell had entered at the top of one shoulder-blade, damaging the spinal column and passing out at an almost symmetrical point on the other. He was very pale from loss of blood and shock, and was painfully affected by the sight of the operating-room with its white-robed attendants and unaccustomed appliances; it is strange how little importance the French attach to details of this kind, as it would have been a perfectly simple matter to anesthetize this man outside in the ante-chamber. The surgeon said to him, speaking through his face-mask: "We are going to give you a little chloroform, *mon ami*, and put that wound on your shoulder in better order." The man seemed to grow paler still, and trembled somewhat; but, summoning what courage he had left after his manifold ordeals, he tried to smile, replied simply: "*Si vous voulez, Monsieur*," and lay back on the table. His condition proved serious, a piece of shell, fragments of bone, and shreds of uniform were extracted from the wound, and his fate now rests in the hands of the gods. If the suppurration from this vast, jagged loss of substance gets into the spinal column, I suppose this gallant son of France will have to go; but if he escapes this danger his chances are good, as the vitality and recuperative power of these men apparently knows no limit. It would seem as though ten months of campaigning in the open had, after sifting out the physically unfit, so tuned up the constitution of the others that they have become as hardy as fox-terriers, animals whose phagocytosis is equal to any terrestrial emergency.

From the one, know them all; this is the French soldier of today. The *morale* of these men is such that their leaders can ask *any* sacrifice from them; and when they fall in the effort, not a murmur escapes their lips. The will-power that enabled that man to summon a smile to his face and utter a formula of politeness as he faced what must certainly to him, and particularly in his grave condition, have seemed a *frightful* ordeal, however matter-of-fact it may have appeared to the operating-room staff, has drawn comment from everyone that has been brought into contact with the French wounded in the ambulances. A young American lady who helps at a base-ambulance in the Vosges told me that she had had to feed with a tube on a passing sanitary-train a young soldier who had been shot in the mouth and was suffering terribly from having to be transported with a shattered jaw. She probably did this with unusual tenderness and skill, for the man was so grateful that he felt called on to make a special effort to express his appreciation; so he summoned up what little he knew of English and uttered a sadly-indistinct "thank you." One of the surgeons on duty at a Paris terminus, where the sorting and distributing of the arriving wounded is carried out, also told me that he went up to a soldier whose condition did not look very brilliant, he having in fact a very bad shell-wound of the right shoulder-joint, and said to him: "*Eh bien, mon ami, comment vous trouvez-vous?*" But all the winning he obtained from that war-victim was: "*Ah, Monsieur, — ce que nous les avons eus!*" (What a doing we gave them.) That fellow was fresh from Notre Dame de Lorette!

The total absence of complaint, the unflinching courtesy, the consideration for each other, and the stoicism with which they accept their lot when hopelessly maimed, although young and with a long life before them of utter ruin,—for when the glamour of the war has worn off, and we all know how quickly that takes place, how unfortunate will not be the situation of these men?—are features that strike the observer with fresh force each time he comes in contact with a different agglomeration of these poor victims. As a surgeon said to me the other day while going along the heels of a ward of forty *grands blessés*, not one of them, even a man that was to pass away that same night, showing signs of discouragement or rebellion against Fate: "With men in that frame of mind, anything is possible." Just one little instance. A shell lit in a French trench, blowing the men and the defences every which-way; finally one *trouper* came to his senses, picked himself up, and shouting "*débout, les morts!*" ("Up with you, you dead beggars!") set to work to rouse others, dig out those buried under debris, and place the slightly wounded in such positions that they could be of help, until he had enough combatants to organize a semblance of defence that enabled him to hold the trench until other troops could get to their rescue.

In fact,—it is a remark made by everyone today that no one seems to know where the present Frenchman came from! The men of my generation, who remember the war of 1870, will also remember the Frenchman of that time; and those who were well-acquainted with the state of affairs here only a year ago, culminating in the disgraceful exhibition of the Caillaux trial on the very eve of this fearful struggle, will also remember that they would not have given a very high purchase-figure for the French moral character at that moment. What, then, has occurred to conjure up the splendid type of manhood that can be seen in any bed in any French ambulance at the present time? Simply this, the alternative of their life or death as a nation. They saw in a moment that *this* time it meant their very existence,—not provinces, or indemnities. At a grave crisis in the history of England one of her celebrated statesmen made use in the House of Commons of words to this effect: "The Angel of Death is abroad in the land"; and, after a long pause, in the solemn stillness he added, "we almost seem to hear the beating of her wings." The same thing occurred in France last August,—the French heard (plainly this time) the beating of the wings of the Angel of Destruction, and in a moment they were changed men: all their frivolity, scandal-mongering, political bickering and general invertebrate condition of *je m'en fiche-isme*, vanished into thin air, and in their place emerged the *men* who have done what the French have done this winter. In the fiery crucible of this the greatest peril of their existence as a nation the dull and unattractive ore has flowed forth as pure and shining metal; nor has the transformation been confined to the men alone, for the women are doing their part equally nobly. In one of the ambulances I visit there is a lady of means who cannot be much this side of sixty, and who for twelve or more hours a day is on her feet moving about incessantly superintending the rooms in which the soldiers' wounds are dressed, lending a helping hand in a thousand different ways. How many young ladies are there who, without previous training, could go straight to such arduous duties as that from the listlessness of social life?

Of the many peoples that are engaged in this Armageddon several have gained undying fame: Serbia did well, and would have done better had she not been stricken to the ground by a pandemic. Belgium did well,—uncommonly well; about this there is no doubt possible. But still,—after making every reserve in favor of these two countries, and admitting that for a small and peace-loving people like the Belgians to stand up against, and bear alone the brunt of, the first onslaught of the greatest military power ever

known, courage and moral fortitude of the very highest order were required.—I think that history will ultimately agree that the greatest surprise in the present struggle has been this wonderful change in the character of the French people, and the unsuspected virtues that have been brought into evidence among them during this terrible emergency.

“S.”

P.S.—I am happy to be able to report that two weeks later the patient mentioned at the beginning of this letter was doing as well as could possibly be expected.

OXFORD AND CAMBRIDGE IN WAR TIME.

(From Our Special Correspondent.)

MERTON COLLEGE,

OXFORD, ENGLAND, JUNE 24, 1915.

Mr. Editor: No places in England show the effects of the war more than the two university towns, Oxford and Cambridge. Both have become training camps as they were in the times of the wars with France. Khaki is to be seen everywhere. One hears bugles from the meadows in the evening and in the morning is awakened by the tramp of marching feet and a song rising from hundreds of throats.

The enrollment of each university has been reduced to less than one-third the usual number. The students seen going about are for the most part Americans and Indians.

Most of the colleges in both universities have turned over a number of rooms to be used as officers' quarters, while in the college gardens one may often see ladies serving tea to the convalescent Tommies.

The First Division Base Hospital in Cambridge is one of the largest and most efficient in England, accommodating about 1200 wounded. It has been built completely since the war began and is composed of long one-story huts whose walls are made of some heavy paper-like preparation. The colonel in charge requested me not to publish a description of the hospital, so I must refrain from further details.

At Oxford the “examination schools,” where at this time last year the university was conducting examinations, now has nearly four hundred wounded. It is called the base hospital. Across the street the Masonic Temple holds about sixty soldiers, while behind the temple an entrance leads into the beautiful gardens of New College. Here several pavilion tents have been pitched and one can see the nurses in their blue uniforms moving in and out among the beds. In the same way the Town Hall has been filled with beds.

At Easter time Major Whitelock was given Somerville, a girls' college, and told to turn it into a hospital. The girls were moved out of their beautiful home and placed in one of the colleges of the university, Oriel. Somerville is now a well organized hospital. More serious cases are placed in the larger wards in the ladies' former dining hall and assembly rooms. For others, three beds are placed in each large bedroom. Dressing tables serve excellently to hold flowers and medicines. The rooms are bright and cheery. Even the gassed patients express themselves as pleased with their surroundings. With a staff of four assisting physicians Major Whitelock is now attending to four hundred cases there.

I overheard the following conversation at Somerville this morning. It was between a young sailor home on leave and a wounded army sergeant. “Ow ‘ave you been getting on in the navy?” “Oh it’s a beastly bore waiting around for something to ‘appen at sea. But ‘ow are you?” For a little while the soldier did not respond, then he said, “I’ll ‘ave a couple of ‘oles in my arm but that’s coming on fine. It’ll be the bloody gas that bothers me. I’ll not feel as though I’ll ‘ave a fit again.” The sailor replied, “This submarineing is nothing to the bloomin’ gas!”

Sincerely yours,

WILFRED G. PENFIELD.

THE DIFFERENTIATION OF BODY TYPES.

SEATTLE, WASH., July 6, 1915.

Mr. Editor: Two recent observations in regard to the herbivorous and carnivorous types of man present an interesting parallel.

In your editorial in the issue of March 4, 1915, appears this paragraph, “Probably the carnivorous type is really the superior, though it encounters peculiar perils in maintaining that superiority, and as a matter of fact it appears, certainly in the majority of American communities, that the carnivorous type predominates. This is evidenced by the rapid evolution, in the second and third generations, of carnivorous types out of immigrants of herbivorous type from European countries.”

In an article entitled “Diagnosis of the Englishman” by John Galsworthy in the *North American Review* for May, 1915, is this statement: “Racially the Englishman is so complex and so odd a blend that no one can say what he is. In character he is just as complex. Physically there are two main types: one inclining to length of limb, narrowness of face and head (you will see nowhere such long and narrow heads as in our islands), and bony jaws; the other approximating more to the ordinary ‘John Bull’. The first type is gaining on the second.”

Very truly yours,

FRED J. FASSETT, M.D.

APPOINTMENT.

Dr. W. F. R. Phillips of the University of Alabama has been appointed professor of anatomy at the Medical College of South Carolina.

RECENT DEATH.

DR. JAMES A. BENNETT, who died recently in New York City, was born at Sterling, N. Y. He received the degree of M.D. from the New York Homeopathic College in 1871, but after practising his profession for a short time, relinquishes it for an active and successful business career. He was the senior living member of the American Institute of Homeopathy and a member of the New York County Homeopathic Society. He is survived by his widow, two daughters and two sons.

ANNUAL MEETING OF THE SOCIETY. JUNE 9, 1915. PAPERS ON PUBLIC HEALTH AND PREVENTIVE MEDICINE.*

(Each speaker being limited to ten minutes.)

I.

THE WORK AND AIMS OF THE STATE DEPARTMENT OF HEALTH.†

By ALLAN J. McLAUGHLIN, M.D., BOSTON.

PREVENTIVE medicine or the scientific prevention of disease is comparatively new. In the days before Pasteur and Koch revolutionized our ideas of the causation of disease, health officers were fighting in the dark, by shotgun methods, against unknown terrors. Every disease and every plague was a mystery in its causation and methods of transmission.

After the establishment of the germ theory on a sound basis, laboratory and research workers all over the world began to work out the problems of the various diseases. In order to fight these epidemic diseases intelligently it was necessary to know the cause and how they were transmitted from person to person. In the past thirty-five years the causes of nearly all the so-

called contagious diseases have been discovered and we have learned how to destroy these germs and prevent the spread of the disease.

We know now that tuberculosis of the lungs is caused by the tubercle bacillus, and that if we could control the sputum of consumptives, the disease would disappear from our statistics.

We know that typhoid fever is due to taking into our mouths with food or drink the typhoid bacillus. In other words, we do not catch typhoid; we *eat* it.

We know that yellow fever and malaria are caused by parasites which can only be transferred from patient to patient by means of a certain kind of mosquito.

We know that bubonic plague is not transferred from man to man, but is a rat disease, and man receives his infection through the medium of the rat fleas.

We know that Asiatic cholera is caused by a germ (because of its shape called the comma bacillus) which is transmitted in the same way as typhoid fever, that is, by means of food and drink.

We know that typhus fever, which is responsible for such frightful ravages in Serbia, is transmitted from person to person by means of the louse, and in no other way. We not only know the cause of disease, but we also know in nearly all cases how these diseases spread. We know that tuberculosis, diphtheria, scarlet fever, measles, pneumonia, whooping cough, influenza, and common colds are spread through discharges from the mouth and nose. We know that if we can keep all traces of intestinal discharges out of our food and drink, we will have no Asiatic

* A paper on Cancer by Dr. Edward Reynolds, Boston, will be found in the Cancer Number of the BOSTON MEDICAL AND SURGICAL JOURNAL, July 15, 1915.

† Read before The Massachusetts Medical Society, June 9, 1915.

cholera, no typhoid fever, no dysentery, and no hookworm disease. We know that vaccination prevents smallpox; that the Pasteur treatment prevents rabies; that inoculations with special prophylactics will protect against cholera, typhoid and plague. We know that diphtheria antitoxin will not only cure diphtheria, but it will also prevent it.

It is evident that what we need is not more knowledge of causation and modes of spread of epidemic diseases, but a more general application of the knowledge we already possess. With this knowledge of how to prevent epidemic disease, why is it that these diseases are still responsible for thousands of deaths each year? Simply because this knowledge cannot be applied without the coöperation of the layman with the health authorities. The attitude of the average layman toward the health department is one of indifference—he feels that some one is paid a salary for safeguarding the public health, and that the citizen has no obligation or concern in the matter. He does not know that the most competent health officer is powerless to reduce disease beyond a certain point without his help.

It is commonly stated that public health is purchasable and this is true, but it is only fair to explain how the purchase must be effected. We health officers speak of preventable diseases, and often neglect to state how, and to what degree, they are preventable. Expert, competent health officers, adequately paid, ample health appropriations, and strong laws will not suffice to eradicate disease unless backed by intelligent public opinion and by the hearty coöperation of the individual citizen. Public health is purchasable, but a large part of the purchase money must be expended in teaching the layman how he may prevent disease by personal hygiene. He must be made to feel that he is an integral part of the health organization, and that his coöperation is necessary to prevent sickness and death among his neighbor. Preventable diseases may be reduced by official action, but can never be entirely eradicated without the support of the layman. An ideal State Health Department should consist of not only the officials on its payroll, but should include all physicians and nurses and every intelligent layman in the State. This ideal may seem far from attainment, but the only way in which it can be accomplished is by means of popular education.

Let us consider what are the big factors in our general death rate and in what way you may help in their reduction. There were over 50,000 deaths in Massachusetts in 1913. About 70% of these, or more than 35,000, were due to the following causes:—

Infant mortality	10,086
Pneumonia	6,124
Organic heart disease	5,402
Tuberculosis	5,402
Cancer	3,526
Apoplexy	3,451

Bright's disease	2,888
Syphilis	?
Diphtheria	628
Measles	315
Scarlet fever	293
Typhoid	280
Whooping cough	239
Influenza	204

These great factors in our problem: infant mortality, pneumonia, organic heart disease, tuberculosis, cancer and the so-called degenerative diseases, cannot be greatly reduced by laws and ordinances, or other purely official activity, and significant reductions in the same can only be effected by the spread of the gospel of right living and personal hygiene through the medium of popular education.

The possibilities in preventive medicine of medical inspection of school children are not being realized as fully or as rapidly as is desirable. There is a lack of a central directing authority competent to ensure uniformity of methods and coördination of effort along the lines of prevention, rather than the detection of disease. Our greatest hope for ultimate success in the suppression of tuberculosis must lie in the prevention of the development of tuberculosis in the child with a pre-disposition for, or latent infection with, tuberculosis. There is also great need for instruction in the diagnosis of tuberculosis before processes in the lungs are present. Teaching of diagnosis in most medical schools is limited to the demonstration of the tubercle bacilli in the sputum and the physical signs in the lungs of well advanced cases. With the development of our system of inspection of school children to its full hygienic possibility, there will be a great need of examining physicians skilled in the newer methods of technic able to make diagnosis with reasonable certainty in the very early stages.

I believe that the time has arrived for a statewide organization of all those interested in public health education. I believe that such an organization should include all health officers and every agency engaged in public health nursing or social service, or the teaching of hygiene in this Commonwealth. Organization is necessary to secure coöperation, to prevent duplication, and to get the full value of the efforts made and the money expended for public health education. It matters little which disease or problem we may be considering, after the health officials have eliminated all the factors which are corrigible by official action, there always remains a group of factors which can only be eliminated by the enlightened coöperation of the individual families or of the individual members of those families.

Health officers are justified in being proud of the achievements in the prevention of disease and the reduction of the death rates which are recorded in recent years, due largely to official activity. We have now reached a point, however, where further progress demands the hearty

support of the individual citizen, and a wider application of the principles of personal hygiene by the individual citizen himself. This means education of the people in their obligations to their neighbors, and in the simple gospel of disease prevention. We have enlisted in this campaign the practising physician as an educator in preventive medicine, and I am confident we may count on his earnest effort and loyal support. There are the great thousands, however, who never or rarely call a physician, and who furnish the bulk of infant and tuberculosis mortality.

I am sure that all practical health officers have found that the greatest defect in the average health organization has been the lack of a medium for carrying effective sanitary instruction into the home. To reach these people, two very effective agencies are in our hands, and great results may be obtained if these agencies are properly directed, so that uniformity of procedure and coordination of effort can be secured under a central authority. I refer to the possibilities of public health or visiting nursing and to the hygiene of school children.

In view of the great reductions already effected in the mortality rates for tuberculosis, typhoid fever, diphtheria, and other diseases, largely due to official activity, it may be said in Massachusetts that further reductions will be in direct ratio to the number of women employed in public health nursing. The successful visiting nurse requires, besides a knowledge of the prevention of disease, tact, patience, and kindly solicitude for the welfare of the poor. Compare the results possible in life saving by the work of such a woman, with the results obtained from the work of the male sanitary inspector, at the same or even at a larger salary.

II.

LOBAR PNEUMONIA.*

By FREDERICK T. LORD, M.D., BOSTON.

It is fitting that lobar pneumonia should head the list of the special subjects under consideration today, since its victims comprise about ten per cent. of the total mortality. The persistently high death rate from pneumonia, in comparison with the encouraging decline in many other of the acute infections, indicates that in spite of our increasing knowledge of the disease the factors of importance in diminishing its spread are not as yet understood or are improperly applied. To avoid the error of failure of application of already existing knowledge to the problem from the point of view of public health it is desirable to consider those features which seem of most importance in this connection.

The influence of the seasons has long been recognized as a most important predisposing factor in pneumonia. The "pneumonia season"

embraces the colder months of the year, and it is worthy of note that this increased incidence of pneumonia at this time coincides with the period of greatest prevalence of all the acute respiratory infections and of exacerbations of the chronic infections. The reasons for this are not wholly clear, but a greater amount of dust, less abundant sunshine and the tendency to live under less satisfactory hygienic conditions, in more crowded and less well ventilated rooms at this season are probably of importance.

Pneumonia is usually regarded as an endemic disease, each case having little apparent connection with other cases. Direct contagion of pneumonia from one person to another cannot often be established. The occurrence of instances of more or less severe local outbreaks are, however, sufficiently common to indicate a mildly epidemic character, which most often become manifest among persons housed in overcrowded quarters as on ship-board, in barracks and in jails. Dispersion of those living in such close quarters may be followed by a diminished incidence of the disease. The infrequency of apparent contagion from one pneumonia patient to another cannot be safely relied upon as an assurance against the communicable nature of the pneumococcus infection upon which the disease depends.

The biology of the pneumococcus is such as to indicate that it cannot long maintain its existence outside the body. It grows only at body temperature and its viability under artificial conditions is short. Like the tubercle bacillus and certain other pathogenic organisms, it can maintain its existence only by passage from person to person. Contagion must then be the manner of spread, and it is only necessary to assume that healthy carriers of pneumococci intervene between one patient with pneumonia and another to understand how transference from person to person may occur.

An interesting and important feature of pneumonia is the frequency with which it is preceded by an acute respiratory infection. Inquiry of patients with pneumonia elicits the history of an acute upper tract infection, commonly ascribed to a "cold," an attack of so-called influenza, or a bronchitis in about fifteen per cent. of the cases, thus suggesting the importance of acute respiratory infection as a predisposing factor.

An important advance in the study of pneumonia has been made in Germany and in this country at the Hospital of the Rockefeller Institute for Medical Research¹ in distinguishing certain types of pneumococci as the infecting agents in the disease. Time does not permit a consideration of the manner in which the strains are differentiated. It is enough to say that there appear to be four types of pneumococci concerned in lobar pneumonia. Types I and II of the Rockefeller classification can be recognized by their agglutinative and immunologic reactions. Type III is distinguished by cultural and pathogenic properties. Type IV is a heterogen-

* Read before The Massachusetts Medical Society, June 9, 1915.

ous group without distinctive agglutinative or immunologic reactions. Of 145 cases of lobar pneumonia at the Rockefeller Hospital observed during 1912-13 and 1913-14,² organisms belonging to Types I, II and III were found in about 80% of the cases. Type IV comprising the remaining 20%. It is to be noted that the different strains show no tendency to change from one type to another under artificial conditions. The identification of these fixed strains is an important advance in the study of pneumonia, and at once affords a more exact comparison of types of pneumococci normally present in the mouth of healthy individuals with those concerned in the etiology of lobar pneumonia.

It has long been recognized that normal persons are carriers of pneumococci in about 50% of the cases. The pneumococci so commonly found in the mouths of healthy individuals, however, differ from the fixed strains most prevalent in lobar pneumonia. Whereas at the Rockefeller Institute about 80% of the pneumonia cases showed the presence of types of pneumococci which could be identified as belonging to groups I, II or III, in a study of 15 strains obtained from the saliva of normal persons not exposed to pneumonia, no organisms belonging to these same types could be found. In a study of 5 strains of pneumococci obtained from similar sources at the Massachusetts General Hospital³ no fixed strains were found. In an attempt to identify the types of pneumococci which occur in the saliva of persons in more or less intimate contact with patients with pneumonia I have investigated 25 persons closely associated as members of the family or nurses. Of this number the attempt to isolate pneumococci was successful in 11 cases, but in none of these did the pneumococci fall into groups I, II or III. In two instances I found organisms which agglutinated with Type I anti-pneumococcal serum, but the morphologic and cultural peculiarities of these two strains indicated that they were not to be regarded as pneumococci. In the remaining 12 cases the attempt to isolate pneumococci failed. Dochez and Avery,⁴ on the contrary, succeeded in isolating typical groups of pneumococci in a number of instances from the mouth sputum of healthy individuals intimately in contact with cases of lobar pneumonia, and in these cases the type always corresponded to that with which the case of pneumonia was infected.

It should be said concerning these observations that they are as yet too few for safe conclusions. They suggest, however, that the strains of pneumococci normally inhabiting the mouth in healthy individuals are less concerned in the etiology of pneumonia than has heretofore been believed. Pulmonary infection with pneumococci resulting in lobar pneumonia has usually been ascribed to increased virulence of mouth organisms or diminished resistance of the host, but now seems more likely to be due to contact with pneumonia patients or healthy carriers of fixed strains of pneumococci. It is probable that

the infective agent in pneumonia is more nearly restricted to the neighborhood of the patient with pneumonia than has been previously thought. In this respect pneumonia may be not unlike epidemic cerebrospinal meningitis, in which healthy carriers of Weichselbaum's meningococcus probably serve to spread the infection.

Measures directed toward the prevention of lobar pneumonia should take into consideration its seasonal incidence at a period when other acute respiratory infections are prevalent and the probable importance of such infections as a factor in the spread of disease producing types of pneumococci. The apparent mildness of its epidemic character should not be allowed to lead to any relaxation of vigilance to prevent transference of pneumococci from person to person. In consideration of the development of pneumococci only at body temperature and their short viability outside the body, contagion must be regarded as the method of spread. The recognition of certain fixed types of pneumococci as the most common cause of lobar pneumonia and the failure to find these same strains in normal persons other than those in intimate contact with pneumonia patients makes it probable that the infecting agent in pneumonia has a more restricted distribution than has been previously thought. More careful control of infected persons may, therefore, be expected to diminish the prevalence of the disease.

The protective value of inoculations with the pneumococcus in preventing subsequent infection of animals with otherwise lethal doses of the organism suggests the possibility of vaccination in man for the prevention of pneumonia. Whether this can be accomplished cannot yet be regarded as settled, but the method deserves an extended trial when in any community pneumonia is unusually prevalent. The experience among the miners on the Rand at the Premier Mine is promising. In 1912, among 17,009 inoculated, the death rate from pneumonia was 6.89 per thousand, while among 6,700 controls the death rate was 17.72 per thousand. It would be desirable in the face of an epidemic to use as a vaccine the strain of organisms giving rise to the infection.

The following recommendations briefly outline the measures which may be expected to diminish the incidence of pneumonia:—

1. Education of the public concerning the manner in which respiratory infections take place and the means of avoiding them.

2. Closer supervision of the acute respiratory infections, such as ordinary "colds," so-called influenza, bronchitis and sore throats, and isolation of the more severe types of these simpler infections when possible.

3. Closer supervision of patients with pneumonia by: (a) making pneumonia a reportable disease, (b) isolation of patients with pneumonia.

4. Avoidance of overcrowding and the regulation of housing conditions.
5. The diminution of dust in cities.
6. Immunization of those exposed in times of epidemics.

III.

INFANT MORTALITY.*

BY JOHN LOVETT MORSE, A.M., M.D., BOSTON.

It is impossible in the few minutes at my disposal to give more than the briefest summary of the main points regarding the importance, causation and prevention of infant mortality. The importance of the subject is shown by the fact that, according to the census of 1910, approximately 265,000 babies in the first and 53,000 in the second year of life died in the United States in 1910, making a total of 318,000. It is hardly necessary to advance other figures. The seriousness of the subject is emphasized, however, when it is realized that a baby comes into the world with less chance to live a week than an old man of ninety, and less chance to live a year than a man of eighty.

The causes of death are shown approximately in the accompanying table:

CAUSES OF DEATH.

Prematurity, congenital debility, congenital defects and accidents of birth.....	25%	}.....40%	}.....5%
Acute gastro-intestinal diseases.....	25%		
Diseases of nutrition.....	15%		
Acute respiratory diseases.....	20%		
Acute infectious diseases.....	3%		
Tuberculosis.....	2%		
Syphilis.....	1%		
Unclassified.....	9%		

It is evident from this table where the work must be done to diminish the present terrible rate of infant mortality.

It seems a self-evident fact that the etiology of a condition must be understood before measures can be taken intelligently for its prevention. This fact often seems to be forgotten, however, in the campaign against infant mortality. Prematurity and congenital debility are, for example, due chiefly to alcoholism or disease in the parents and to overwork and under-nutrition of the mother. The measures to be taken to remedy these conditions are obvious, but far-reaching. Among them are the abolition of alcoholism, the prevention and notification of venereal diseases, the regulation of the employment of pregnant women, the provision of proper food for pregnant women, prenatal care by public nurses and by prenatal clinics, and the provision of suitable hospitals for the

care of premature infants. Most of the injuries at birth are avoidable, and are the result of the neglect or incompetency of physicians and midwives. The remedies are the better education of physicians, the abolition or proper regulation of midwives and the establishment of free municipal clinics for the care of poor women in labor.

The diseases of nutrition and the acute gastrointestinal diseases are due primarily to bad feeding. In general, 85% of all infantile deaths are in the bottle-fed and 90% of the deaths from the diarrheal diseases are in the bottle-fed. The remedy is again obvious. Women must be taught to nurse their babies and measures taken to enable them to do so. Public aid must provide for the mothers so that they do not have to wean their babies to go to work. They must be fed and helped. This can only be done when there is compulsory birth notification, which is enforced.

The bottle-fed babies die because they are badly fed. They are badly fed because of the ignorance of mothers and doctors, the inability of the poor to get good milk and their inability to take care of it, if they get it. The remedies are again obvious. They are the better education of physicians in the matter of infant feeding, the education of the poor and ignorant classes by district nurses, milk stations and "consultations," the improvement of the milk supply in general, the provision of clean milk for babies by public and private charities and the provision of free ice in the summer.

Other causes of the acute diarrheal diseases are excessive heat, overcrowding, unhygienic surroundings and flies. The remedies are again obvious. Among them are the improvement of the living conditions of the poor, the provision of parks, piers and playgrounds and the suppression of flies.

The causes of the acute respiratory diseases are overcrowding, bad ventilation and debility from improper feeding. The remedies for these conditions have already been mentioned.

The other causes of infant mortality are relatively so unimportant that it is hardly worth while to take them up, except to say that tuberculosis in infancy is due either to direct contagion or to the milk from tuberculous cows. The remedies are again obvious. The babies of tuberculous parents must be separated from them. The public must be still further educated to the danger of the infection of infants by adults suffering from open tuberculosis. The sale of milk from tuberculous cows must be prohibited or, if this is not possible, all milk must be pasteurized.

It is evident from what has been said that the fundamental causes of infant mortality are poverty, ignorance and immorality. Poverty, ignorance and immorality are always with us and are unfortunately widespread. It is evident, therefore, that the problem of the diminution of the infant mortality is a very broad and com-

* Read before The Massachusetts Medical Society, June 9, 1915.

plex one. It is no simple matter to correct the morals of the public, to educate the ignorant and to relieve poverty. Much has been and is being done, however, to diminish the infant mortality and the results of this work are already evident in a decreasing death-rate, especially in our large cities. Much more must be done, nevertheless, than is now being done. To do it means the expenditure of much energy and money, especially of money. The money spent will, however, be well invested, because of the increase in the productive power of the community as the result of the number of lives saved. The campaign is too large a one to be properly carried out by private charity. It must, therefore, be undertaken and conducted by the public authorities, national, state and municipal.

IV.

THE CONTROL OF TYPHOID FEVER.*

BY MARK W. RICHARDSON, M.D., BOSTON.

TYPHOID fever is with us because typhoid bacilli get into our food and drink. Typhoid bacilli get into our food and drink because the stools, urines, or sputum of persons harboring typhoid bacilli are inadequately controlled. Not all persons, however, who ingest the typhoid bacilli contract typhoid fever. They are either naturally immune or have, through typhoid infection or through artificial inoculation, acquired specific immunity. The problem resolves itself, therefore, into two parts: First, a more strict control of typhoid excretions; and, secondly, an increase in the resistance of the community through typhoid inoculation.

TYPHOID INOCULATION.

The value of this procedure has been demonstrated beyond a doubt through military experience and the results obtained in training schools for nurses. The immunity acquired is not absolute in all cases. It persists for three years and probably longer. The inconvenience suffered by the individual is small. The necessary material is furnished free of charge by the State Department of Health. The practice should become universal because it will be long before typhoid excreta can be eliminated from our water and food supplies.

CONTROL OF WATER SUPPLIES.

The character of the water supplies in Massachusetts has improved enormously in the last forty or fifty years, and to this improvement, no doubt, is due the fact that the typhoid death rate in this state, which in 1870 was approximately 80 per 100,000 of the population, is now but 8 per 100,000. This improvement, however, is confined largely to the urban water supplies.

The water supplies of the farms, exposed as they are frequently to contamination from defective privies and barnyards, continue to be responsible for much typhoid fever, especially of the vacation type.

There should be undoubtedly much more close supervision over the country well, not only from the point of view of the inhabitants of the rural localities, but also from that of the summer visitor.

CONTROL OF FOOD-HANDLERS.

Another very important factor in the control of typhoid fever lies in an increasingly strict supervision of food-handlers. The dangers incident to an unclean cook have been well exemplified in the experience of the New York Health Department with Typhoid Mary. It is apparent, however, that efficient control can be obtained only after long years of effort and mainly along educational lines, for it is manifestly impossible to determine, even by frequent bacteriological examinations, all the individuals who may be excreting typhoid bacilli. An important beginning, however, can be made if Health Departments will undertake the examination and education of all typhoid convalescents. Urinary carriers of the convalescent type are practically constant and easily discovered. Fecal carriers are, unfortunately, intermittent and not so easily discovered. In my opinion, however, the urinary carriers are much more dangerous. All typhoid convalescents, and especially those having to do with food products, should be made the subject of special educational effort, for with knowledge and care these individual carriers can reduce their dangerous potentialities to a minimum.

It has been my fortune to examine many cooks, to see many hotel and club kitchens, to see the lavatories used by these cooks, and their methods of furnishing specimens of urine and, to me, the wonder is that we do not have more typhoid than we do.

There is on foot a strong movement looking to the periodic examination of food-handlers in order to further the elimination of communicable disease. Such examinations, if supplemented properly by educational work would undoubtedly have an important effect upon the transfer of infection through food products. The necessity for an adequate inspection of milk, its production and distribution, seems to me to lie largely in the elimination from the industry of those who are sick or have been sick with a communicable disease, through the proper care of excreta of such individuals.

The house fly and his relation to diarrheal diseases has been abundantly exploited. I believe that this exploitation has been somewhat overdone, but would, nevertheless, urge a continued active campaign against this common nuisance.

* Read before The Massachusetts Medical Society, June 9, 1915.

THE TYPHOID PATIENT.

All cases of undetermined continued fever should be reported immediately to the local board of health as possible cases of typhoid fever. In no other way can health departments take early and effective steps to control epidemics.

To clear up the diagnosis, the physician must then use all the aids furnished by city and state authorities, such as Widal outfits and bile outfits for the cultivation of the typhoid bacilli from blood, stools, urine, or sputum. All doubtful cases should be subjected to typhoid precautions. Typhoid patients are best treated in hospitals. In any event, those who care for patients should not also be concerned with food supplies.

All excretions should be treated with disinfectants, the best of which is heat as employed in steam-jacketed hoppers used in large hospitals or as generated through the decomposition of calcium oxide in the method of Linenthal and Jones. Chemical disinfection is best carried out by thorough mixing of the excreta with carbolic acid 5%, formalin 10%, milk of lime or chlorinated lime 6%. Disinfection should, furthermore, be extended to bath water, inasmuch as this can easily be contaminated with stools or urine. Internal disinfection through the use of hexamethylamine should be carried out in every case, five or ten grains of the drug being given three times daily throughout the disease. This drug has no effect probably upon the presence of the typhoid bacilli in the stools although it is excreted in the bile. As a urinary disinfectant, however, it is very effective and eliminates undoubtedly many of the urinary carriers. Incidentally, I believe it prevents the occurrence of intercurrent cystitis, orchitis, and epididymitis.

The typhoid bacilli are present but rarely, I believe, in the sputum. I have seen them but once and then during a complicating pneumonia. This undoubted occurrence, though uncommon, necessitates, however, the routine disinfection of all sputum. It requires, furthermore, that each typhoid patient should have his own dishes and other apparatus, and that they should be subjected to rigid supervision. The disinfection of typhoid excreta from a city point of view is required from another standpoint, in that many of our shell fish are grown or fattened in sewage-polluted waters. Such polluted waters, furthermore, are oftentimes used by the public for bathing purposes.

DISINFECTION OF PREMISES.

After the death or convalescence of a patient, the room or rooms in which the patient has been kept must be the subject of careful treatment. Gaseous disinfection of the premises, however, is neither necessary or advisable. Sufficient will be done if the rooms are treated with a maximum of fresh air and sunshine with the abundant application of soap and water and the maximum utilization of fire, steam, boiling water

and some chemical disinfectant, such as carbolic acid 5%.

Finally, perhaps the most important factor in the whole problem is that of unclean hands. We have seen that the typhoid carrier, through unclean habits, infects oftentimes the food supplies. Of similar importance are the unclean habits of the general population, which as a rule takes no care to wash the hands before partaking of food.

When we consider how many typhoid carriers are at large, how frequently they must contaminate objects of common contact, such as door-knobs, hand rails, etc., it cannot but be that the indirect transfer of infectious material to the hands of the general population is frequent.

Indeed, I believe that our most effective slogan for the immediate future must be *wash your hands before handling food, whether it be for yourself or for other people's use.*

V.

PREVENTABLE HEART DISEASE.*

By ROGER I. LEE, M.D., CAMBRIDGE, MASS.

THE discussion of preventable heart disease is inevitably the discussion of the etiology of heart disease. Dr. Richard C. Cabot¹ in an analysis of six hundred successive and unselected cases of heart disease found that he could group 93% of the 600 cases under four etiological headings. These headings were: (1) Rheumatic, that is, presumably streptococci, (2) Syphilitic, (3) Arteriosclerotic, (4) Nephritic. The largest group was the rheumatic or streptococci, which includes 278 cases, or a little over 46%. The next largest group was the nephritic group, 19%; the arteriosclerotic was 15%; the syphilitic 12%. It is evident that the so-called "rheumatic," that is the streptococci or infectious group, is the important group. It embraces nearly half of the cases. Streptococci heart disease has its origin in a large majority of cases (in 60% of Cabot's series) before the 22nd year. It begins young; it is essentially a chronic disease and if severe or progressive it handicaps those afflicted during the prime of life, and often kills before maturity. The prognosis of severe chronic endocarditis in childhood is notoriously grave. Surely it would seem that since it is possible by repeated adequate medical inspection to control the health of school children, it ought to be possible to eliminate much of this group and to minimize the after-effects of early slight cardiac lesions. Even on economic grounds a considerable number of people should not start their working years with a handicap which can never be removed, but which tends to increase.

During the past year opportunity presented to examine the entire freshman class of Harvard College. This group represented 662 young

* Read before The Massachusetts Medical Society, June 9, 1913.

male adults of an average age of 18. The individuals were not selected but the group may be considered to be selected in so far as it is always a selected group as to parentage, social environment and intelligence that seeks an academic education. This group represents theoretically young men who have had the best medical advice. Actual invalids are naturally not to be expected in this group. Of these 662 students 13, or approximately 2%, had a definite lesion of one or more valves of the heart. There were two additional cases in which there was some question of valvular trouble. In 10 of the 13 cases the mitral valve was affected, in two of the cases the aortic valve, and in one both the mitral and aortic valves were affected. In every case the heart was perfectly compensated, and it might be assumed that if the lesion progressed no further there would be no serious handicap to moderate activity.

A study of the histories of these cases showed that five out of the thirteen, or 38%, gave a definite history of rheumatic fever; one case had had it twice. In one case the cardiac condition dated definitely back to the milk epidemic in 1911. He had tonsillitis and rheumatic fever at that time, and subsequently developed not only an endocarditis but persistent albuminuria. None of the other cases presented albuminuria. Eight of the cases gave a history of severe tonsillitis, two of the cases had had pneumonia. One youth had had both pneumonia and rheumatic fever. Another had scarlet fever at 11, pneumonia at 15, and three attacks of tonsillitis. His endocarditis might have originated from any one of these infections, or a combination of two or more. Four of the cases had had scarlet fever. Only one case gave a history of no more serious infection than chicken-pox, measles and whooping-cough. That case had had some operation on the tonsils at 10 but the tonsils were still present. Seven of the thirteen cases had had some operation on their tonsils. However, 43.5% of the whole group of 662 freshmen had had some operation on the nose or throat, so that the increased percentage of cases with valvular defects with tonsilleotomy was hardly striking. One of the thirteen cases had obviously large tonsils, another had buried tonsils. Removal was advised in both cases.

In order to contrast the rheumatic history in the group with valvular defects, which showed a history of rheumatism in 38%, the histories of the other 649 cases were analyzed. Thirty-five of these presented a history which might be interpreted as rheumatic fever. The interpretation was very liberal and certainly included all the possible cases and probably a considerable number of cases that should not be so classified. This gives us a percentage of 5% in the group without valvular lesions as contrasted with 38% in the group with valvular lesions. Furthermore, there were two young men who gave a history of rheumatic fever and who had hearts that seemed enlarged according to clinical ex-

amination but without other signs of valvular disease. It seems not unlikely that these two students had a slight endocarditis. The importance of rheumatic fever, which has long been recognized as an important etiological factor in valvular heart disease, is thus confirmed. Rheumatic fever is not always associated with endocarditis. It is possible to have rheumatic fever without endocarditis and endocarditis without rheumatic fever. It is probably true that rheumatic fever, like endocarditis, is only one of the results when bacteria, usually of the streptococcus, pneumococcus group circulate in the blood. The initial disease which permits the entrance of the organisms may be scarlet fever, pneumonia, tonsillitis, or any other infection. The essential point of emphasis is that to prevent valvular disease of the heart it is important to prevent antecedent infections which result in endocarditis. In one case the method of infection was patent. The case was acquired during a milk epidemic and could have been prevented by the use of pasteurized milk. The method of infection of the other cases was not apparent. The tonsils seemed to be accused as the atrium of infection in the majority of cases on account of the history of previous tonsillitis. Pneumonia and scarlet fever were in other cases probably the immediate etiological factor. Therefore the prevention of all the acute infections, particularly those associated with tonsillitis and rheumatic fever, seems to be the preventive treatment of valvular disease of the heart.

In Dr. Cabot's classification syphilis of the heart caused 12% of his series. Syphilis is an infection and the emphasis must be laid not so much on the prevention of cardiac manifestations after syphilis as the prevention of syphilis itself. Granted the existence of syphilis in a given case, the importance of thorough treatment of that case, not only to prevent cardiac and other complications, but also to prevent the spread of syphilis is obvious.

Evidence is slowly accumulating, tending to demonstrate that arteriosclerosis is dependent in a large measure upon the toxins of certain infections. That arteriosclerosis is due to lead is undoubted, that it may be due to other similar poisons is possible, but at present the evidence points definitely that arteriosclerosis may well be due in the large majority of cases to the toxins of the various infections. To my mind the prevention of arteriosclerosis lies in the prevention of infections with their toxins and the prevention of the introduction of other poisons like lead, rather than in the modification of habits of living and diet. The importance of proper habits and diet in the treatment of arteriosclerotic disease is, however, well recognized.

In the nephritic group we are dealing again in the large majority of cases with the end result of an infection, working not directly on the heart, but on the kidneys and thus on the heart. How often does a nephritis date back to an

early scarlet fever? Even in the degenerative form of nephritis the infections play an important rôle in causation as they do in arteriosclerosis.

The introduction of new methods of precision, the polygraph, electrocardiograph, the Roentgen ray, the sphygmomanometer, the complement fixation test for syphilis have all contributed to a more accurate differentiation of cardiac disease. In consequence of this change of criteria, it is probably true that we have eliminated fully as much as we have added. For example, it is now possible to interpret many cardiac irregularities and to exclude them from actual cardiac disease. Tea, coffee and tobacco are the frequent causes of cardiac irregularity but not of cardiac disease. Many cases of the so-called cardiac disease, so diagnosed on account of irregularity, are now known to be only functional disturbances of rhythm and not cardiac disease. Another popular fallacy has been that participation in athletics caused cardiac disease. Dr. Cabot was unable to find any such case in his series of 600. Mackenzie² in England has protested against this fallacy and says he has never seen a case of "athletic heart." I have personally seen many cases of so-called athletic heart, but have failed to find them abnormal. I have recently studied the effect on the heart of rowing, and have failed to find evidence that prolonged participation in rowing for a period of ten years damages the normal heart.

CONCLUSIONS.

Most heart disease is due to an antecedent infection. The prevention of heart disease is the prevention of infection. While it is true that certain infections like the tonsillitis-rheumatic fever symptom-complex group and syphilis are particularly associated with cardiac disease, yet logically every infection may be regarded as a possible carrier of damage to the heart. There does not seem to be adequate appreciation of the possible sequelae of infections, particularly rheumatic fever. Continued supervision after infections is important in order that an early endocarditis may be detected and the resulting damage be minimized. At present the development of medical inspection and supervision of school children seems the next step.

The prevention of infections is an enormous problem, but must be faced. It is possible to control better scarlet fever and syphilis. It is possible to make milk supply reasonably safe, and it is possible to remove diseased tonsils. It is the fashion now to remove tonsils in as many school children as possible. It is still an open question as to the desirability of removing moderately large tonsils in the absence of history or evidence of disease processes in or connected with the tonsils. While further legislation may be of assistance, the true solution of this problem can be found in the proper appreciation by the public and the medical profession of the

danger of all acute infections. The avoidance of infection and the prevention of its spread is largely a matter of personal hygiene. The department of health can and does supply the necessary information. The utilization of this knowledge depends on the intelligent coöperation of physicians and the public.

VI.

TUBERCULOSIS: THE POLICY OF THE STATE OF MASSACHUSETTS REGARDING TUBERCULOSIS.*

BY ARTHUR K. STONE, M.D., BOSTON.

It has been repeatedly asserted, especially at legislative hearings at the State House, that Massachusetts has no policy regarding tuberculosis. This assertion has been made, not only by laymen and lawyers, but also by physicians who should have known better, and therefore I am going to take this opportunity to set before the members of the Massachusetts Medical Society the policy of the state, which has been developed by careful study and enacted into law by the legislature.

The first idea in the legislative mind in dealing with the tuberculosis question in Massachusetts was to provide a place where consumptives could be cared for, and Rutland was started, not as was intended, but as a sanatorium. Later the three new state hospitals were built, again with the expectation on the part of the petitioners and the legislature that they, too, for the most part would take care of the far advanced cases. But the pressure for beds for cases who hoped for cure was so great that they became filled with moderately early cases; and yet the demand for the care of the far advanced cases was just as insistent as before; nay, more insistent, for the people had to a large degree come to look for hospital care for their advanced cases, having been educated to the danger of contact with them. Massachusetts was already well in the forefront of states in the tuberculosis campaign, but there was steady pressure for more opportunities to care for the unfortunate.

Accordingly, the legislature of 1910 directed that a commission should study the needs of Massachusetts and report to the following legislature. This commission, headed by Drs. H. P. Walcott and A. T. Cabot, with Dr. R. I. Lee as secretary, went over the whole ground most thoroughly, and made various recommendations, which became embodied in a series of laws and amendments to existing laws enacted by the legislature of 1911. Briefly, the policy then established was as follows:—

It is the duty of the state to care for three classes of tuberculous patients: First, state wards, that is those persons by any chance un-

* Read before The Massachusetts Medical Society, June 9, 1915.

der the authority of the state, either in its asylums or prisons, who are found to have tuberculosis; second, those persons of foreign birth who have no legal settlement in any municipality of the state; and third, those persons who are at such an early stage in the disease that they are best treated in accordance with the most approved sanatorium methods. It was recognized that in every way so far as possible, it was desirable to separate these early, incipient cases from all contact with advanced cases and to treat them intensively.

There still remained the great group of advanced cases to care for,—cases which must have protection and care; patients who are discouraged, who want to be near familiar scenes and friends, and yet who through advancing weakness are unable to care for themselves and thus become a consequent menace to those about them. It seemed desirable to take care of these patients as near their homes as possible, and the law requires that all cities shall provide for the care of its tuberculosis patients, either in a separate institution, or by arranging with a nearby city for such care; or several cities may unite in hospital construction. In addition, towns on request of the department of health, may be included in this act. This is a necessary provision as will be seen when one considers that we have a community of 40,000 people living under so-called town government.

In order to help the municipalities in their work of hospital construction, the state has guaranteed to subsidize each town or city by the payment of five dollars per week for each patient maintained in a hospital that has been approved by the Board of Trustees of Consumptive Hospitals; and in the last year Massachusetts paid out about \$129,000 for the care of such tuberculosis patients. A subsidy is practically given to all patients, for the state charges but four dollars per week for patients in the various sanatoria, while the actual cost to the state is about ten dollars per week.

Further to encourage people to go to the various hospitals, it is provided that persons in hospitals and sanatoria for tuberculosis, when they cannot pay themselves, their board is paid by the health department of the municipality in which they have legal residence, and they are not pauperized by receiving such aid.

That the patients may be found early, when the probability of cure is greatest, it has further been enacted into law that the cities and all towns of 10,000 inhabitants shall maintain a dispensary, which has been defined to include a suitable room, a doctor, and a dispensary nurse. Here people who fear the disease can go and be examined, and can receive advice and help in case of need. Here, too, can be referred the person leaving the sanatorium, so that the very necessary "follow-up" work can be carried out to the greatest advantage and the work of the sanatoria made more effective. The dispensary nurse and the school nurse may be combined in

some communities, and in all they should work in harmony so that cases of tuberculosis may be discovered in children through these two agencies, for it is the consensus of opinion at the present time, that many, if not the majority, of cases of tuberculosis receive their primary infection in childhood, breaking out later during the stress of work and modern life.

Thus Massachusetts has a very definite policy as regards tuberculosis, and one that I believe to be most excellent and one that, in general, we physicians should support enthusiastically.

It has been asked, Why should not the state care for all the cases of tuberculosis as it does for the insane? Would not the state hospitals be better run—less in politics—than municipal institutions? This has been the contention of the Fall River Chamber of Commerce, which has been the most severe critic of the state policy. The Board of Health and the Board of Trustees of Hospitals for Consumptives, as directed by the Legislature of 1912, and the Recess Committee of the Legislature of 1913, who again reviewed this ground most thoroughly, were not convinced that it was desirable to change the policy of the state, and recommended various amendments to the existing laws, which affected them in detail only.

The great importance of the care of the advanced tuberculosis patient in the municipal hospital is, to my mind, the educational argument. The advanced case is a menace to the community. He should be in a hospital, if possible, for his best care, and secondly for the protection of the community. The hospital should have attractive features which should appeal to both the patient and his friends. It should be easy of access, that the friends may be able to visit frequently and thus maintain an interest in the patient. They should feel a personal responsibility for the institution. The board by whom it is run, and the doctors connected with it, should have personal interest in the whole problem, and the citizens should have the details of the work and the need of it brought to their attention each year in the annual reports and budgets, which will show emphatically the frequency of this disease in the community; for it is only when a community is awake to the ravages of tuberculosis that there is any hope of eradicating the disease.

Then, too, it must be remembered that the township is the political unit of New England, and that towns and cities included in artificial boundaries have often very distinct individualities differing from those of an adjacent town or city. Hence, it is often hard to get coöperation between towns and cities, when to the casual observer there should be no reason why such towns or cities should not unite to advantage to build combination hospitals for their patients. In most cases, I am sure that the best results will be gained if the municipality faces its problem and builds a hospital which shall care for its own advanced cases.

Two rural communities have appreciated the needs of their people and have come forward and asked for special legislation to enable them to construct a tuberculosis hospital. This broad-mindedness was first exhibited by Hampshire County, which, containing only one city (Northampton), asked and received permission to build, and has built a hospital for the tuberculosis cases in its county. This group of towns had a population of about 63,000 persons. This year Barnstable County (the Cape Cod towns) was given permission to construct a hospital for tuberculosis and a hospital for contagious diseases; and Cape Cod has only about 30,000 inhabitants, scattered in small villages from Provincetown to the canal. Certainly these people should be an inspiration to other communities to look after the sufferers within their boundaries.

In a few instances it is a hardship for a small city to build a hospital which will be difficult to run economically. It is a recognized fact that an efficient hospital unit is about forty to fifty beds; below that number the overhead charges are too great for economy; and above that the general service soon has to be doubled to make for efficiency. In some instances, such problems may best be met by arranging a hospital for a group of towns combined with the city in question; and in other cases, by having two or more neighboring cities unite to build a hospital in common, or by having a contract made between the city building the hospital and its neighbors whereby they agree for a rental and a definite per patient cost to send their patients to the hospital. The city of Malden has expressed a willingness to accommodate in this manner one or two of her neighbors.

Here, however, comes difficulty in regard to municipal jealousy and distrust, and such combinations are going to be difficult to arrange; and if this idea of combination is to be carried out, some further legislation will have to be enacted, giving somebody (probably the Public Health Council) power to arbitrarily combine cities and towns into groups for the construction of hospitals for tuberculosis patients.

There is need of these hospitals at once. There are patients already for the beds. There are long waiting lists at all the state sanatoria. Patients not unfrequently pass from the incipient and early stage before they can be admitted to the institutions that are especially designed for the cure of the early case. These state sanatoria have done good work, but never the work which they are capable of doing, because they have not had the truly early case to deal with exclusively.

The reporting of cases of tuberculosis, which is a part of your duties as physicians, is not carried out as it should be. Recently, I was told by a physician in a city of about 35,000 inhabitants and having 25 doctors, that there were approximately 60 cases of tuberculosis reported in that city, of whom a quarter had been reported

by himself. He did not believe that he had that proportion of the tuberculosis work of the city. In too many towns and cities the reported cases are yet fewer than the number shown by the mortality statistics. This should not be; the town and city officials and the State Department of Health should know of the extent of the disease throughout the state. It is your duty to see that this law is carried out; and it is only when the extent of the problem is known that the laymen and city officials will be ready to meet this important problem.

Let every physician realize that Massachusetts has a state-wide policy regarding tuberculosis, that it has been carefully considered and devised to meet the needs of the political life of the state, and that this policy should be enthusiastically supported in its general lines, and that any amendment should be to meet certain specific difficulties rather than to consider any change in its general construction.

VII.

SYPHILIS.*

By ABNER POST, M.D., BOSTON.

As affecting the public health, syphilis must be considered as a great deal more than simply a venereal disease. It is a communicable disease, chronic, lasting many years, intermittent, disappearing for a time so completely as to simulate a cure, only to reappear later in some cases in more serious forms. (In fact, certain pessimists affirm that it is incurable.) It is infectious in its earlier stages. Later stages are hardly communicable at all. In fact, it was believed some years ago by many that its later or tertiary stages were never communicated. The continued existence of its microscopic entity in tertiary disease is now positively known, and, in consequence, the possibility of infection; but practically the cases of infection from tertiary disease are very rare.

From the standpoint of preventive medicine it is very necessary to distinguish between the dangerous cases and those practically harmless. If the recent infectious cases can be rendered innocuous the spread of the disease will be wonderfully diminished.

The knowledge that syphilis is largely venereal in its origin has led to the attachment of a stigma to all syphilites. This has made the syphilitic resort to clandestine medication, to advertising doctors and advertised remedies. A curious mental condition in the community has led to the refusal of hospital relief to syphilites. A feeling that syphilites are unfit for Christian charity seems to be an underlying sentiment. In addition it has been considered that their condition was the result of their own acts, and their relation to the public health has been ignored. One of the results of this condition of public

* Read before The Massachusetts Medical Society, June 9, 1915.

opinion has been its reaction on the medical profession. It is one of the diseases which students have very largely been allowed to pick up. In few medical schools has it been systematically taught. Although hospitals have refused to accept such cases, cases have crept in. They are admitted under false diagnoses, and in that manner they falsify the hospital reports. Rheumatism, tuberculosis and cancer are but some of the diagnoses under which syphilites are admitted. Hospital reports of diseases treated have been greatly reduced in value by the failure to recognize the diagnosis of syphilis. A similar condition exists in private practice. It is a brave man who dares sign a death certificate giving syphilis as the cause of death. All sorts of evasions are resorted to, all of which tend to invalidate vital statistics. The vast number of cases in which the disease is discovered by the Wassermann reaction in the laboratory is strong evidence of neglect of clinical study.

Various remedies have been tried for the control of syphilis:—

1. Registration and license of women of the town is the one largely pursued in European countries. That system is based upon a wrong principle. It is believed by many to be a failure in practice. It is impossible of execution in this community.

2. Expatriation, or the driving out of that class of women who are supposed to have spread the disease, has been tried in various communities. No community can follow that method for any length of time. For to drive them from one place is only to drive them into another. It is also based upon the theory, which is erroneous, that one sex alone spreads the disease.

3. Compulsory registration is proposed and has been tried to some extent. It is too early for such a procedure. With present ideas it could only favor concealment and deceit on the part of doctors and patients alike, and recurrence to clandestine medication, to advertising doctors and advertised remedies.

In this community we have tried neglect and refusal to recognize even the existence of the disease. It has so flourished that it is no longer possible to ignore it. It demands our serious attention. If we can extinguish or control the fresh infections we can safely neglect the later cases, so far as danger to public health is concerned. It is certainly with fresh or infectious cases that we ought to concern ourselves. Fortunately these are the easiest cases to deal with. These cases are rendered harmless, for a time at least, by a single dose of 606—not necessarily forever harmless, nor are they always absolutely cured. But it certainly diminishes their danger wonderfully. A single visit with the immediate administration of 606 is worth a dozen visits otherwise treated with other treatment, so far as danger to the community is concerned. Unfortunately for the State, we compel these patients to pay for their own treatment. This they can-

not always do at a moment's notice. The treatment is postponed and the patient disappears untreated. The State ought to take advantage of the first visit by free and immediate treatment. It is a wonderful opportunity.

Salvarsan is not necessarily the best remedy possible. It will doubtless be supplanted by a drug more easily obtainable. But it has demonstrated the fact that the spread of syphilis is more easily controlled than was possible earlier. If this drug becomes unattainable, some other combination will undoubtedly take its place.

The laws at present on the statute books are sufficient for present control. They obligate cities and towns to care for such cases, and allow no hospital supported wholly or in part by taxation to discriminate against the disease unless by provision of a special hospital. They provide for the arrest and custody of anyone with a disease dangerous to the public health, under the law which permits the removal of any person who is a menace to the community.

Failure to provide medical care for the children who have inherited or acquired syphilis is construed by the courts as cruelty to children, under the physical neglect law.

The retention of all inmates of public institutions while they are a menace to public health is provided by law.

We do not need more laws, but the enforcement of existing laws. A change in public sentiment is already beginning.

The Massachusetts General Hospital has maintained for nearly two years a separate department for syphilites, with large out-patient facilities and a few beds. The Boston City Hospital has practically done the same thing. The Children's Hospital has changed its policy and now treats children with syphilis. The Boston Dispensary has for many years paid considerable attention to these cases. Worcester has provided a hospital ward for their care. The Psychopathic Hospital has done very much to spread a knowledge of the disease in its cerebral manifestations, and while not called upon to take measures which shall prevent its spread, has been caring most watchfully for those cases which ought to be very largely prevented by such care of earlier cases as has been here recommended. The Massachusetts Medical Society devoted a forenoon to the subject last year. The New York State Medical Society at its last annual meeting instituted a separate section and devoted three days to the disease.

The Post Office has done much to protect credulous sufferers against unscrupulous advertisers, but no one of these agencies has gone so far as to consider it the duty of the town or state to make itself responsible for the curing of the patient. We are still inclined to regard the syphilitic from the viewpoint of the moralist rather than that of the pathologist. We still act as if the disease was communicated by immorality alone and its dangers were confined to the immoral.

From the standpoint of protective medicine and public health, the following matters would seem to be indicated for the present:—

To recognize syphilis as a communicable disease.

That it presents problems for the physician which should not be entirely given over to the eugenicist and the moralist.

That cases should be provided with hospital care.

That the best means available for treatment and cure of early cases should be provided by the community for such individuals as are unable or unwilling to provide it for themselves.

That the disease should be regarded as a subject worthy the most careful study of physicians and students.

These means would meet with no opposition. They would go far towards controlling the disease and prepare the way for more vigorous measures later.

VIII.

CONTAGIOUS DISEASES.*

BY EUGENE R. KELLEY, M.D., BOSTON.

STUDIES upon contagious or communicable diseases and attempts to control them represent the oldest branch of preventive medicine. For all practical purposes, until quite recently, the consideration of "contagious diseases," "general sanitation," and "vital statistics" covered the entire field of preventive medicine. As the bacterial concept of communicable disease transmission became better established the prodigious amount of detailed, technical study and investigation, involved in both the laboratory and administrative side of preventive medicine, tended naturally and inevitably to create a group of specialists. From this it was a most natural development for the general public and the medical profession as well, to consider the whole question as one for the specialists to concern themselves with,—as one that did not affect them at all. Only today are we fully beginning to realize that if the old glib phrase, "contagious disease control" is ever going to be something more than a phrase—is ever going to become an index of fact rather than a figure of speech—we must change about radically and point out clearly and unmistakably to the people that the control of contagious diseases is impossible so long as it is considered a subject which concerns the hygienists and the medical profession alone.

The most encouraging thing about the subject of communicable diseases is the rapidity of the progress that has been made in the fight against them in the immediate past. It is not putting it too strongly to say that until the past half-century mankind made little intelligent advance in the problem of contagious disease control. While

several significant discoveries and advances, one epoch-making, were made during centuries of observation, the true nature of the cause of contagion was still wrapped in impenetrable mystery. Without this fundamental knowledge, all deduction, all epidemiological observation, all the intellectual forces of mankind went hopelessly astray when brought to bear upon the problem. Since the discovery of the bacterial concept of disease by Pasteur, however, real solid advance has been most rapid. For example, in this country since 1880, the first year in which figures for any portion of the United States outside of Massachusetts became available, and the year in which the United States Registration Area was established, the mortality for that portion of the United States admitted to this area from certain prominent communicable diseases has dropped as follows:—

Typhoid	50%
Scarlet fever	89%
Diphtheria	84%
Tuberculosis	54%

For the beginnings of scientific disease prevention in America, it has come about that the Massachusetts Medical Society can claim the eternal credit of having been responsible in no small measure through the individual studies and profound foresight of certain of its members and the enlightened stand taken by it as a corporate body.

The question that most concerns us now is—Where does Massachusetts stand in the question of communicable disease control today—what further reductions in the prevalence of these diseases can reasonably be expected of the future—and how can such reductions be brought about?

The achievements of this state in the past twenty years are most striking. The reduction in the main has been steady and consistent; and the bare figures speak louder for themselves than any embellishment can ever do. The fatality rate from typhoid fever has been reduced nearly 75% in twenty years, and the actual typhoid fatalities from 680 typhoid deaths in 1895 to 234 deaths in 1914; the fatality rate from diphtheria has been reduced over 80%, and the actual diphtheria fatalities from 1784 in 1895 to 601 in 1914; the fatality rate from consumption has been reduced nearly 50%, and the actual consumption deaths from 5486 in 1895 to 3362 in 1914. These facts are an enduring monument to solid achievement in true preventive medicine. The cold statistics serve to call up to the imagination of hygienists and physicians the hundreds now living that without this advance would be in cemeteries—the thousands now in the joy of health and strength that otherwise would have suffered from these scourges.

But when we come to certain other common contagious diseases, we do not find the record either so clear or so satisfactory. Scarlet fever,

* Read before The Massachusetts Medical Society, June 9, 1915.

while showing on the whole a reduction, is so variable in its frequency and fatality that we cannot make any such confident assertions as we can for those diseases mentioned above. Measles and whooping cough, those diseases considered so negligible by many of our fellow citizens, but known by us to be so serious, show no reductions that are not followed by periods of corresponding increases, the measles fatality rate for the last year of our twenty-year period being almost exactly twice the rate for the initial year of that period. To these we may add those other great variables of epidemiology, infantile paralysis and cerebrospinal meningitis. It is evident that there still remains something to be done in the control of communicable diseases.

Neither can Massachusetts claim any marked superiority over the other states in the degree of completeness of contagious disease diminution, except in the matter of typhoid reduction. The practising physicians in Massachusetts reported last year (1914) 7144 cases of pulmonary tuberculosis, 2333 of typhoid, 11,057 of scarlet fever, 12,264 of measles, 3316 of whooping cough, and 8080 of diphtheria. These facts are enough to indicate that the control of contagious diseases is still a problem worthy of our most serious consideration. Can we solve it?

Within the assigned limits of this paper, we can only consider in barest outline the means which we can look to in our attempt to reduce communicable disease prevalence:—

1. First of all must come a better education of the general public, particularly parents and educators, as to the real nature of contagious disease transmission. To a great extent the public mind is still focused on environment rather than upon living beings, whether human, animal or insect, or, in short on the inanimate rather than the animate world, as the prominent factor in communicable disease transmission. To prove this point, we need only note the blind reliance the general public still place in fumigation and the slowness with which they grasp the conception of direct disease transmission through the naso-pharyngeal or alvine discharges.

2. We must have more efficient diagnoses. Improvement here has been consistent, I believe, although perhaps slow. A wider and prompt use of the diagnostic laboratory is one great aid that the physicians of this State should have more readily accessible in many portions of the State than is the case at present. But it cannot be said that the facilities of the present laboratory systems are utilized to the extent they might well be. Take diphtheria, for example. If any clinical fact is now well established, it is that there is no specific clinical picture of a beginning diphtheria. The physician should try out by culture any suspicious throat, particularly if diphtheria is known to be present, and not wait until the clinical picture is typical and then send a culture. Nor should a single laboratory negative in suspected diphtheria, tuberculosis, or

typhoid cause the physician to relax his clinical vigilance. The fact that a single laboratory report is negative is no better evidence that the disease is not present than the fact that we fail to catch any fish in a given stream on a given day is evidence that the stream contains no fish.

3. Another factor of great importance is prompt reporting to the authorities, so that they may investigate and assume control as early as possible. Every single case of contagious disease can be regarded in only one light, viz: as a potential focus for an epidemic. It is a fact worthy of record that the physicians of Massachusetts today report a higher proportion of cases when compared with the mortality figures than probably any other state in the Union.

4. Following the reporting comes logically efficient isolation—efficient isolation is at its best in hospitalization. The need of hospitalization varies with many factors. Of all our contagious diseases it is most urgent in the case of tuberculosis because of the chronicity of the disease and the insidiousness of infection. It becomes less necessary as we go up the social scale and as the density of population decreases, for obvious reasons,—but whether our isolation be at home or in a hospital, the modern tendency is strongly away from “shot gun” quarantine policy, and towards an enlightened contagious disease “asepsis” for the sick room, leaving those who do not come into direct contact with the patient a much greater freedom.

Other means of contagious disease control which deserve consideration at length, but which we will only mention, are:—

- (a) Hygienic supervision of schools.
- (b) The use of specific sera for cure, detection and prevention.
- (c) Protection of food supplies.
- (d) Venereal prophylaxis.

This in brief is the program we must follow to achieve our aim. The part played by the medical profession must continue to be, as in the past, one of unselfish curtailment of certain sources of their own revenue; and in addition one of much greater utilization of their teaching capacity in their dealings with the public, and of support for the public health administrators in their oftentimes disagreeable duties.

If we can do this I feel that it is not unreasonable to predict at least a 10% further reduction of tuberculosis frequency and fatality in the next ten years; at least 50% diphtheria decrease; as much typhoid and epidemic cerebrospinal meningitis decrease; a substantial, although I will not venture to predict how great, reduction for measles, scarlet fever and whooping cough; and a hope that we may be able to do something more satisfactory than we have hitherto done against infantile paralysis.

SPOTTED FEVER OF THE ROCKY MOUNTAINS.

By G. F. POPE, M.D., WINNEMUCCA, NEVADA.

1. *Etiology.* Geographical distribution: For about thirty years this disease has been known in the Valley of the Bitter Root River, situated in Western Montana. A few cases have also been observed in other parts of that state. In Idaho the disease has been pretty generally found at different times, especially in the southern part of the state, along the Snake River and its tributaries. In Nevada, the Quim River country, Buffalo Valley and along the Humboldt we find it pretty generally distributed. Also in parts of Eastern Oregon it is found in a mild form.

2. *Season.* It is a disease of springtime and early summer, as early as the middle of March and as late as the first of August. It is never seen at other times of the year, and it seems to come with the ticks and go with the ticks.

3. *Climate.* The disease does not prevail south of 40° latitude or north of 47° latitude, and seems to be prevalent in elevation of about three to five thousand feet above sea level.

4. *Occupation.* It infects individuals whose occupation takes them into the open sage brush country, such as stock men, common sheep herders, miners, prospectors, lumbermen, and those who are exposed to the bite of the tick.

5. *Age.* I have seen it in a child of five and in a man of sixty-four.

6. *Sex.* In fifteen cases, five were females and ten males.

7. *Blood Examination.* One hundred and fifty blood smears in fifteen cases have been studied and no parasite has been found: in each case Jenner's or Wright's modification of Jenner's stain has been used. This would seem to disprove the findings of Wilson and Chowning; and Anderson's work at Mazula, Montana, which verified Wilson and Chowning's discovery of a parasite in the blood, was disproved by Styles and Ricketts.

8. *Method of Infection.* On investigation it is found that all the patients had been bitten by ticks, some of them many times, and that the disease comes as the ticks come in the spring and disappears when they leave in late summer. As to intermediate host, it is generally believed among old ranch men that sheep are the most common hosts and that there never was a case of spotted fever before the advent of the sheep industry into these mountain states. This would seem to be carried out by experience. But Ricketts has very satisfactorily proven that many other animals may act as intermediate host in this disease,—the ground squirrel, cattle, horses, rabbits, and indeed any of the animals which

rove these great ranges. The first case in the state of Nevada occurred in the year 1874, and was thought at first to be a case of smallpox. I must, of course, refer to those most valuable experiments of the late Dr. Ricketts of Chicago— inoculation experiments, which proved that immunity was established by the artificial production of spotted fever in guinea-pigs. This experimental work, I was unable to carry out. From the examination of a number of ticks found in the neighborhood of cases of spotted fever, I have found the most prevalent form to be *Dermacentor Venustus* of the classification of the Bureau of Entomology of the United States Department of Agriculture.

9. *Symptoms. Incubation:* This is from three to ten days, usually seven. There may be a few days of general malaise, with chilly sensations, nausea or a distinct chill, and the patient takes to bed. Generally there is pain in the back and all the muscles and bones feel sore. Or the symptoms may be much exaggerated and the limbs feel as if in a vise; bowels are always very constipated throughout the disease; tongue heavily coated, with red edge and tip; conjunctivae congested, becoming yellow; urine small in amount, of high specific gravity, with albumen and sometimes casts; little bronchitis after a few days and nose bleed is present in all cases.

Fever. Before the distinct chill there is a little or no fever in the morning, but a slight rise of temperature in the afternoon. Then the course of the fever is just like an ordinary typhoid, with gradual rise in the evening, and morning remission. The maximum is usually reached on the tenth to the twelfth day; then gradually falls to normal, in favorable cases, on the fifteenth or eighteenth day. The temperature may get as high as 104 or 105, with slight morning remissions.

Circulatory System. The pulse is that of an average typhoid, and blood pressure in one well nourished adult of twenty-five after the first week dropped to ninety and stayed there for two weeks. Blood examination showed a progressive decrease in the red cells, with increase in the number of white cells from 15,500 to 17,000. A differential count made in three cases showed an average as follows:—

Polymorphonuclear leucocytes	80.2
Large mononuclear leucocytes	10.0
Small lymph leucocytes	9.0
Eosinophiles8
	100.00

Widal's reaction negative in fifteen cases examined.

Eruption. The eruption usually appears on the third or fourth day of the disease and is seen first on the wrists and ankles, then on the soft palate and uvula, then on the legs, arms, forehead, back, chest and abdomen,—on the abdomen least abundant, but literally covering

other parts of the body. The spots at first are of a reddish salmon color, macular at all times, and about the size of a split pea. At first they disappear readily on pressure and come back to their original color quickly; after a time they become darker and darker, until they are of a distinct purple. By the tenth day of the disease they fail to disappear on pressure and are petechial in character. In about fourteen days they begin to lose their petechial character and disappear slowly on pressure. When the fever begins to go the eruption begins to fade, but a return of fever, free perspiration or exposure to a cool breeze will bring out these purplish spots again. This peculiarity may last for weeks or even months after convalescence. The skin may be quite fair, but a slight perspiration with sudden exposure to a cool breeze will bring out the purple spots at the site of the old eruption. I never have seen any well defined desquamation after the disease, but this may be due to the fact that I use boric acid, sponging constantly through the febrile period. In neglected cases when nutrition is poor and bathing is not well carried out, we may have necrosis of the skin over the different points of pressure, and in other cases a sloughing of the soft palate. The skin is always jaundiced, the conjunctiva congested and yellow.

Digestive System. There is white coating of the tongue with red edge and tip, later sordes on the teeth and lips. Appetite is fair during the first week, but nausea may be a marked symptom and last to the end. Constipation is always present and is very marked. Some tympanites is usually seen. The spleen becomes enlarged early and may extend two inches below the costal margin.

Urinary System. The urine is reduced to about half the normal amount in twenty-four hours, with little albumen and casts.

Respiratory System. There is always a little bronchitis, and lobar pneumonia is a frequent complication. Epistaxis is seen in the first days.

Nervous System. Pain in the back and head is marked during the first week of the disease. Patients change position frequently because of the soreness in muscles and bones. The mind is usually clear, even in the severest cases and the pupils react normally.

10. *Treatment.* The treatment is purely symptomatic. It consists in the use of high enemata, when necessary to keep the bowels free. Feeding should be in the form of large quantities of easily digested food, peptonized milk, chicken broth, toast, eggs in any form and ice cream. I have been using a liberal diet as follows: for breakfast, at 6 A.M., farina, one portion with lactose, one and one-half ounces and cream, one and one-half ounces; bread and butter, two ounces without crust, one egg, coffee, five ounces, with cream, one and one-half ounces, and lactose one ounce. Eight o'clock, hot milk, six ounces, with cream, one and one-half ounces, and lactose,

one ounce, bread and butter, two ounces. Dinner at twelve, broth 8 ounces, bread and butter in form of milk toast, two ounces, with milk, six ounces and cream one and one-half ounces, lactose one ounce, eggs poached, two; rice, one portion with cream, one and one-half ounces, lactose, one and one-half ounces; 2 P. M., ice cream one portion, bread and butter two ounces, milk six ounces with cream one and one-half ounces. Supper at 6 P.M., wheat breakfast food, one portion, with cream one and one-half ounces, lactose one and one-half ounces, bread and butter two ounces, cocoa, two cups with cream; 8 P.M., orange albumen, made from the white of two eggs and one-half ounce of lactose.

Tepid sponge baths of saturated solution of boric acid are continued throughout the disease every six hours as long as the temperature is over 102. Mouth and teeth receive careful attention by the use of tooth brush and gargling with liquor antisepticus, U. S. P., every six hours. Internally I have found quinine to be useless if not harmful and I have contented myself with the use of five grains of salol every six hours. The boric acid tepid bath, as in small-pox, seems to lessen the congestion of the skin and favor the course of the disease, at least I have thought that it did and I know that patients derive much comfort from this form of treatment. Undoubtedly the future will bring to us some form of vaccine treatment which may be of distinct service in a disease having the etiology of spotted fever.

Medical Progress.

PROGRESS IN GYNECOLOGY.

By STEPHEN RUSHMORE, M.D., BOSTON.

MENSTRUATION.

In the investigation of pathological uterine bleeding, a point of view to which, in general, little attention is paid, according to Novak,¹ is that which looks first for the cause of normal uterine bleeding or menstruation. This is especially of importance in cases where no obvious anatomical basis is found, for in normal menstruation there is no evident cause for the escape of blood into the uterine cavity. Neither the changes in the structure of the endometrium, as hyperplasia, nor changes in the muscle, as in the so-called uterine insufficiency, nor in the blood vessels, as in arteriosclerosis, will throw light on the group of cases which is to be explained.

On account of recent studies of internal secretion and the various organs which somewhat definitely contribute this element to the body economy, the following theoretical explanation of menstruation may be formulated:—

1. There is first some underlying cause (or causes).

2. There is a nervous mechanism, essentially vasomotor in nature, determining pelvic congestion, and

3. There is the terminal mechanism, the uterus and especially the endometrium.

The causes of uterine bleeding may, therefore, be divided into three groups:—

1. Fundamental, including disturbances of internal secretion of the ovary or of some other gland;

2. Nervous causes exerting influence through the vaso-motor system; and

3. Anatomic causes, affecting structural changes in the pelvic organs, blood vessels or even the blood itself. It is the first and second group that Novak discusses.

In the study of the fundamental causes of menstruation, one is confronted at the outset by an enormous literature containing few facts. This means that so far, difficulty has been experienced in studying the ovarian function. Certain changes clearly follow removal of the ovary or cessation of its function. But increased ovarian function cannot be produced, nor is it recognizable in its manifestations. Recently the problem has been attacked by Adler from the point of view of the sympathetic nervous system. Here two functions are evident, called after the analogy of the nervous mechanism of the heart, sympathiotropic, referring to the accelerator action on the heart, and vagotropic or inhibitory.

Certain chemical substances, including hormones, exhibit a special influence on one or the other of these two systems. Epinephrin is an example of the sympathiotropic group, pilocarpin of the vagotropic. Adler has found in some cases of "ovarian insufficiency" as at the menopause, heightened susceptibility to small doses of epinephrin; and in some cases of uterine bleeding, a heightened susceptibility to pilocarpin. A certain amount of confirmation has been given by Novak from cases of his own. The conclusion that ovarian hyperfunction is the cause of the bleeding in these cases is only suggested, not proved, for the complete mechanism is so very complicated. Experimental work also has suggested rather than proved the presence of other factors in the cause of uterine bleeding, as changes in the coagulability of the blood when it reaches the uterus, the effect of other glands of internal secretion, and finally, the effect of the "nervous" causes, which includes impulses from the higher centers. Although in the case of menstruation there is no evidence of voluntary control, yet psychic factors may play a part, as is well known clinically.

Blair Bell² has made a chemical study of the menstrual blood in two series of cases, in order to determine the presence of fibrin ferment and of fibrinogen. In the first series of cases the menstrual blood did not clot; in the second, clotting was present. He found in the former

series neither fibrin ferment nor fibrinogen in any case. In the latter cases fibrin ferment was nearly always present; fibrinogen only a few times. He concludes, therefore, that it is the presence of the fibrin ferment that determines the clotting, and if this is absent clotting will not take place. But his search for the cause of the disappearance of the fibrin ferment has so far been in vain, though he says that it or its precursor is removed or destroyed by some vital process in the cells of the endometrium.

In the Hunterian Lecture by H. Beckwith Whitehouse,³ he has presented a study of menstruation which deserves careful attention. It is comprehensive and as detailed as the limitations of such a lecture would permit. It represents a contribution to our knowledge of the physiology and pathology of hemorrhage from the uterus. The non-coagulability of the menstrual blood represents the chief points investigated by Whitehouse himself. Normally the blood may clot in the uterus but a fibrolysin is apparently present in the fluid of the menstrual blood, not, however, capable of resolving an unlimited amount of thrombus. It is thought by Whitehouse to be secreted by the glands of the uterus. The tissues of the endometrium contain, on the other hand, thrombokinase. The balance between these two factors is upset in the functional hemorrhages of puberty and of the menopause. In normal women it is easily disturbed, as is shown by the fact that in about half the cases investigated small clots were found in the menstrual blood though it did not clot. The original lecture should be consulted for the details of the experimental work which constitutes the basis of Whitehouse's contribution, presented in an interesting and scholarly manner.

DYSMENORRHEA.

Doederlein⁴ presents a good resumé of the various views on this subject which have been advanced by different investigators. While in a general way it is clear what is meant by the term clinically, the cause of the symptom and its significance are obscure. There is often gradual onset, with colicky pain and headache, nausea and vomiting. Between periods the patient is usually perfectly comfortable, though occasionally "mittelschmerz" occurs, of unknown significance. There is sensitiveness of the inside of the uterus, especially the internal os, and in the menstrual discharge may be found some of the cast off endometrium, according to Doederlein's statement. No satisfactory explanation of the cases is forthcoming, yet the increasing prevalence of the disease in America suggests as an etiological factor defective sexual hygiene, in the matter of regard for the physiological disabilities and weaknesses of girls in the critical period of development. The psychoneurotic factor is receiving more attention as a possible explanation, while local physical changes seem of less importance. Prophylaxis involves

sociological problems difficult of solution. Curative treatment should be both general and local. Hygiene, diet, tonics, rest, should be supplemented by opotherapy. Dilatation of the cervix, the use of stem pessaries and systematic sounding of the uterus have proved efficacious. Perhaps the favorable results here are due to dulling the sensitiveness of the uterine mucosa. During the attack applications of heat, sitz baths and hot douches with drugs (hydrastis, viburnum and opiates) to relieve the severe pain of uterine contractions are useful. In a number of cases latent tuberculosis has been discovered, and this possibility should always be kept in mind, whether the patient be of the robust or of the anemic type.

X-RAY IN THE TREATMENT OF MYOMATA.

The question of whether surgery can be eliminated in the treatment of myomata of the uterus is discussed at some length by McGlimm.⁵ On account of the growing, and, as it seemed to him, mistaken tendency to treat myomata by the x-ray, he wrote to a number of surgeons and roentgenologists in this country, asking their opinion on various phases of the subject. The replies, confirming in general McGlimm's opinion, form the basis of his article.

Reports favorable to the x-ray are due to failure to take into account the high percentage of cures by operation; practically all cases are cured that recover from the operation. The low initial mortality of the x-ray treatment must be counterbalanced by late failures. Besides, it is exactly those cases with complications, which chiefly give the operative mortality, that are deemed unsuitable for treatment with the x-ray. Other elements to be considered are the dangers from the x-ray, which are not limited to simple dermatitis; the inability to determine whether a given case is suitable for x-ray, as complications often cannot be made out clearly before operation; and the possibility of malignant change. Operation, with myomectomy as an alternative to hysterectomy, in certain cases of young women who desire children is more conservative.

On the other hand, there is no doubt that roentgenotherapy has controlled bleeding and in a certain number of cases has reduced the size of the tumor. Yet it can actually take the place of surgery in only a small proportion of cases. Its special field is those cases which are poor surgical risks, or in which operation is refused. If anemia alone is the contraindication to operation, x-ray may be used to check bleeding until the patient can be suitably prepared for operation.

RADIUM THERAPY.

The cases of uterine hemorrhage reported by Kelly and Burnham⁶ fall into three groups.

- 1 Metropathies (myopathia hemorrhagica),
- 2 Metrorrhagia in the young (soon after puberty), and

3 Polypoid endometrium.

Myomata of the uterus, in some of which no hemorrhage had occurred, were also treated. The interesting results obtained are worthy of notice: the hemorrhages generally ceased and the tumors disappeared or diminished in size. The preferred method of application is intra-uterine as it is more efficacious and less likely to produce complications. Just how valuable this addition to the armamentarium of the gynecologist is, it is impossible to say as yet. Perhaps not as important as the authors say, for their claim that it is "perfectly suited to secure the disappearance of fibroid tumors" is vitiated by the fact that one case, in which the uterus was only ten centimeters in diameter, had to be subjected to radical operation. That is, one in a series of 21 cases. But we have, at any rate, a method that may prove of great value, and in the hands of those who can obtain the radium and are competent to use it, should be more widely tested before resort is had to operation.

PROLAPSE OF THE UTERUS.

The multiplicity of operations for prolapse of the uterus indicates that no single operation has been found which is always satisfactory; and when the variety of anatomical conditions is considered it is not to be expected that one method of procedure will suffice. Lenormant and Petit-Dutaillis⁷ describe an operation which is suitable for a certain number of cases. It is completed by a colpo-perineorrhaphy which exhibits no new feature. The treatment of the cervix and the anterior vaginal wall is the characteristic element. The operation consists of an extensive quadrilateral resection of the anterior vaginal wall, in fact, nearly one-half of the entire circumference of the vagina, and a high amputation of the cervix. It is, therefore, applicable only to those cases in which there is incomplete prolapse of the uterus, with hypertrophy of the cervix. The prolapse is cured by amputating somewhat more of the cervix than projects from the vulva and building up the perineum to give additional support to the stump of the uterus which is left. No effort is made to support the uterus from above. It is suitable, therefore, only in those cases in which an abdominal operation is inadvisable or refused and the body of the uterus still remains in the pelvis.

Guthrie and Whiteis⁸ describe a simple method for curing prolapse of the uterus, whether complete or incomplete, which presents the disadvantage, however, that the possibility of future pregnancy must be removed. The principle is to supply a large surface over which support is afforded to the uterus by suturing the body of the uterus into the abdominal wall between the recti or outside of them. The operation is usually attributed to Kocher and in its application the authors vary some of the details. While such an operation may fix the fundus perma-

nently, and in some cases also cure cystocele and rectocele, the general experience would point to the necessity of accessory operations below to support the bladder and rectum more firmly than can be done by a lifting process from above.

As a result of Nyulasy's⁹ experience, he holds that the chief structures supporting the uterus are its ligaments, principally the cardinal ligaments, and that the pelvic floor is of secondary importance. He has devised an operation in accordance with this view, for the cure of prolapse of the uterus, which has, in a general way, the same effect as an operation advocated by Dudley some years ago, though the operative procedures are different. In each case it is by bringing the base of the broad ligament, the cardinal ligament, forward on the cervix, that the support is obtained. Nyulasy opens the abdomen, frees the bladder from the uterus, dissects out the cardinal ligaments, making sure of the position of the ureters, and sutures each ligament to the cervix anteriorly by a silk thread. In his diagram he shows a single suture of silk catching both ligaments and a bit of the cervix. The round and utero-sacral ligaments are also shortened.

The advantages are (1) practical absence of hemorrhage, (2) the excellent immediate anatomical and almost certain good permanent results, (3) comparative absence of post-operative shock, and (4) the absence of raw areas as the incision between uterus and bladder is closed by a running suture of catgut.

RETRODISPLACEMENT OF THE UTERUS.

Byford¹⁰ says the operation which anatomically has proved most satisfactory in bringing the fundus forward in cases of retrodisplacement of the uterus is that known as the Alexander. In certain cases it needs to be supplemented by other procedures as shortening the utero-sacral ligaments or the use of a pessary for a short time following operation. But it is least likely to do harm and give rise to complications later. The objection to it, and formerly this was its greatest recommendation, is that the peritoneal cavity is not opened and thus intraperitoneal complications cannot be dealt with, or sometimes even discovered. Byford has sometimes employed it even after making a median incision on account of such complications. But the operation he suggests makes the usual lateral incisions unnecessary. The important steps are first to make a loop of the intraperitoneal portion of the round ligament distal to a point about three centimeters from the uterine cornu. By suturing the sides of the loop together a double cord is made. The peritoneum is separated from the abdominal wall from the median incision to the internal ring, at which point it is punctured from without inward. Through this puncture the loop of round ligament is drawn and then sutured by a perma-

nent suture to the under surface of the abdominal wall, about one centimeter from the ring. The technic is simple and easy, the immediate effect is good and the intraperitoneal effect is practically as after an Alexander operation.

According to Reynolds¹¹ in many cases of retroversion of the uterus, the cervix not only lies closer to the symphysis than is normal, but either it cannot be displaced backward, or if it is so displaced by considerable force, it immediately springs forward when the traction or pressure is released. There is present what seems to be a shortening of the anterior vaginal wall, but the displacement forward of the cervix is due, not to the anterior vaginal wall, a soft yielding tissue, but to the underlying connective tissue and fascia, the Y ligament of Goffe. The retrodisplacement of the fundus in these cases has taken place because at the time of menstrual congestion the uterus tends to become straight, due to a simple hydrostatic law. If, then, there is relaxation of the round ligaments, or if the straightening is sufficient to push the fundus to the point where intra-abdominal pressure is exerted on its anterior wall, the fundus goes into retroversion.

The treatment of the fascia which fixes the cervix forward is the point of Reynolds' contention. He recommends a transverse incision in the vagina just anterior to the cervix, going deeply enough to completely sever the fascia. The incision is closed in a direction parallel to the long axis of the vagina. This lengthens the anterior wall of the vagina but the crucial point is the severing of the fascia. If this is done the cervix easily goes back in the pelvis and the operative procedure can be completed by any of the ordinary methods of suspending the uterus.

URINARY INCONTINENCE.

Kelly and Dumm¹² discuss urinary incontinence in women without manifest injury to the bladder, give a description of various operations noted in the literature, report a series of cases from Dr. Kelly's clinic and describe an operation which has given good results. The object of the operation is to narrow the opening of the bladder into the urethra, for often, and generally, it is the sphincteric action which is feeble. An oval denudation, four by three centimeters, is made in the vaginal mucous membrane over the neck of the bladder. The exact position of the internal sphincter is determined by introducing a Pezzer or mushroom catheter into the bladder and making traction until it impinges firmly on the bladder wall at the opening of the urethra. It can be easily felt through the wall of the bladder after the denudation has been made. At this point the tissue on each side of the median line is grasped by two or three mattress sutures of silk or linen thread and approximated under the urethra. The closure is made with a continuous suture of fine catgut. The operation in Kelly's hands has

given complete control in a large percentage of cases, and may be performed under local anesthesia if indicated.

UTERINE ENDOSCOPY.

The desirability of seeing the inside of the uterus has many times appealed to the gynecologist, for other methods of investigation so often leave the operator in doubt as to whether a hysterectomy is or is not indicated. Bimanual examination, the uterine sound, digital examination (rarely possible) leave much to be desired. Heineberg¹³ describes a uterine endoscope which consists of (1) endoscopic tube, (2) irrigating attachment, (3) obturator, and (4) lighting attachment, and presents a preliminary report of a few cases which he has examined. The normal findings are given and the technic described. Dilatation of the cervix to 46 French is necessary for satisfactory introduction of the endoscope. In the presence of pregnancy or acute inflammation the procedure is contra-indicated. General anesthesia is necessary on account of the dilatation of the cervix, but perhaps local anesthesia can be made to suffice. While its use as a routine is not likely to be of much value, there are certain cases in which it might be a very valuable adjunct in diagnosis.

LEUCORRHEA.

Curtis¹⁴ has carried out a thorough study of a series of cases of chronic leucorrhea making bacteriological examinations and employing various methods of treatment. In non-parous women, purulent discharge is rare apart from gonococcus infection. In parous women additional factors play a part, as infections associated with pregnancy, altered anatomical relations acting as a predisposing factor, and increased secretion of mucus. Purulent discharges come chiefly from the lower portion of the tract and rarely from the body of the uterus. In virgins the vagina contains few bacteria except the large Gram-positive vaginal bacillus described by Doederlein. In married women bacteria of various kinds and in varying numbers are found. But in infected cases profuse purulent discharge and many bacteria are found often.

Smears and cultures from leucorrhoeal discharges show a preponderance of anaerobic bacilli. While streptococci and staphylococci are occasionally found and the pseudo-diphtheria bacillus is as yet of unknown significance, a Gram-positive diplococcus is a constant finding. The gonococcus is of course of great clinical importance but it is often difficult to distinguish in vaginal smears. Perhaps its rôle in chronic disease is in preparing the soil for the leucorrhoea-producing anaerobic bacteria.

In considering treatment, certain features should be emphasized: (1) The uterine cavity tends to remain free from bacteria; (2) excessive mucus not only increases the amount of

discharge but also acts as a culture medium for the bacteria; (3) the discharge usually originates in the lower portion of the tract; (4) in most cases there is a decreased local vitality and an associated low grade infection.

Therapy, therefore, should be directed to the improvement of the lowered resistance of the genitalia. Not only may lacerations need operation, but systemic conditions demand attention. There should be strict avoidance of treatment which is not definitely indicated or which will injure the tissues. Curettage of the uterus should not be performed. The cervix, however, may be dilated to give better drainage. Douches would seem to be ill-advised, and tampons have been generally discontinued. Scarification of the cervix and cauterization with silver nitrate, 20%, followed by dry powder may diminish the secretion from this source. Residual gonococci may require specific treatment and are difficult to dislodge. Vaccine treatment has been on the whole the most satisfactory method of treatment, giving a fair percentage of cases cured. A most encouraging feature of the vaccine treatment is the relief of backache and general malaise. The various powders give immediate improvement but there is a marked tendency to recurrence.

INOPERABLE CARCINOMA TREATED BY HEAT.

Percy¹⁵ again calls attention to the value of heat in the treatment of inoperable carcinomata of the uterus, which as a matter of fact comprise a large percentage of all the cases seen. In spite of the vast amount of study of cancer we still know too little of it to institute etiological therapy and we have to fall back on some means of destroying the growth. It has been found that in spite of the unduly active proliferation of cancer cells, they are more susceptible to the influence of certain injurious chemical and physical agents than are normal body cells. One of these injurious influences is radioactivity. But for several reasons the field of application is limited though as yet these limits have not been exactly defined. Another agency that will inhibit and destroy carcinoma is heat. In recent years this ancient method has been tested in the laboratory, and it has been found that *in vitro* cells from malignant growths are killed at a lower temperature or are killed more quickly at a given temperature than are normal body cells. It was noticed, too, by Vidal that in several patients with a temperature above 104°, tumor growths were arrested. This led to animal experiments which confirmed Vidal's clinical findings. As a result, Vidal put forth the statement that experimental methods of treating cancer have been effective only when there has been a febrile reaction on the part of the patient. Perhaps the cases of malignant growths which have disappeared after an attack of erysipelas are to be explained in this way. It is found, however, that the margin of safety between the heat necessary to destroy the car-

cinoma and that dangerous to the patient is small. Methods of raising the general body temperature are therefore impracticable. The only agents which have been found so far worthy of consideration are hot air, hot water, steam, electro-coagulation, fulguration and the actual cautery. Hot air, hot water and steam have too little penetrating power. Electro-coagulation requires a special apparatus, a refined and delicate technic and is difficult to control exactly. Fulguration is more satisfactory but perhaps its effects are from heat alone. Still more satisfactory than any of these, on account of the simplicity of apparatus and relatively slight expense, is the actual cautery. By means of special devices in the way of a controlled electric heating iron, a water cooled speculum and a vaginal dilator, inoperable carcinoma of the uterus can be treated with much better results. It is important not to use intense heat as that causes charring and greater likelihood of complication afterward. Several applications may be made and the procedure would be useful as a preliminary to radical abdominal operation. In one case noted by Percy, no carcinoma was found in serial sections eight months after treatment in accordance with this technic. The use of the curette should not be combined with the cautery as the curette tends to cause metastases. As occasionally a late hemorrhage has occurred after the treatment, it may prove advisable to tie the uterine or even the internal iliac arteries previous to the heat treatment.

VAGINAL AMPUTATION OF THE CORPUS UTERI.

The use of this operation is increasing and series of cases are reported by Jung¹⁶ and by Loehnerberg.¹⁷ The chief indication is bleeding from the uterus, usually with no obvious cause, which has resisted other forms of treatment. From an economic point of view it is generally to be preferred to x-ray or mesothorium, and it gives a certain cure without much operative risk. The danger of malignant disease in the stump is not great and the method is to be preferred to vaginal total extirpation. The symptoms of the menopause were less marked than after the removal of the ovaries. In some cases the menstrual function persisted, but with greatly diminished flow, and in general the results are very satisfactory.

EUGENICS AND GYNECOLOGY.

Veit¹⁸ calls attention to the folly of hasty conclusions and ill-advised legal methods of control advocated by some "eugenists." While in theory eugenics demands action, in practice there is as yet too profound ignorance of heredity to make it clear just what action should be taken. The occasion for Veit's discussion of the subject was the presence in his clinic of two patients, one of whom, a chondro-dystrophic dwarf of 35 gave birth by Cesarean section to a fine normal child, while the other, a girl of 18,

"pretty as a picture," gave birth naturally to a dead anencephalus. The paper does not lend itself well to condensation but it is a rather comprehensive plea for making haste slowly in the matter of practical eugenics and is to be commended for the wise sanity to be expected of one of Veit's experience.

INFANTILE UTERUS AND PREGNANCY.

The condition of infantile uterus and appendages is generally regarded as giving a bad prognosis for pregnancy. Elliott,¹⁹ however, reports a case in which, following treatment, pregnancy ensued. Another physician had told the patient that she could never have a child as "the uterus was about the size of an English walnut and the ovaries were not palpable." Though the patient was 27 years of age and had been married five years, she had menstruated only three or four times in her life and then only slightly. Corpus luteum tablets were given for several weeks, with massage of the uterus. As the patient noticed very little change, she discontinued the treatment. Three months later the lutein tablets were again started. About two months later pregnancy began and the patient was in due time delivered of a normal child. Before the pregnancy ensued there had been increased menstrual flow and some increase in the size of the uterus as well as a slight change in the general outlines of the body toward a more pronounced female type.

HIGH RECTO-VAGINAL FISTULA.

A case presenting this rather unusual condition with several interesting features is reported by Eden²⁰ and discussed at length. The patient, aged 41, was admitted to the hospital soon after her fifth confinement, which had been an easy low forceps delivery, complaining of complete incontinence of feces. At first all the fecal material passed per vaginam; later some escaped per anum. Following the fourth confinement the patient had been operated on for prolapse and extensive laceration of the cervix. Examination showed that the uterus was fixed, anteverted, and the cervix which had no posterior lip apparently opened into the fistula. The fistula admitted two finger tips and presented its greater diameter transversely to the vagina. The size and inaccessibility of the fistula and the fixing of the uterus indicated the difficulty of the operation. First a preliminary colostomy was performed. This was very satisfactory for the lower bowel collapsed and was easily kept clean though after three weeks the fistula had shown no sign of healing. Hysterectomy seemed indicated as it would give further assistance in exposure and suture, and the abdominal route was selected. The uterus, including all that was left of the cervix was removed. The fistula was then closed transversely to the long axis of the bowel and the first line of suture covered by a flap of vagina. The peritoneal cavity was then

closed off completely from the area below. The operation was long and the patient left the table in some shock but rallied well. The colostomy was doubtless an important factor in giving the fistula opportunity to heal and was closed four weeks after the closure of the fistula by resecting two and one half inches of the gut and doing an end to end anastomosis. Three months later the condition of the patient was quite satisfactory.

Book Reviews.

A Manual of Personal Hygiene by American Authors. Edited by WALTER L. PYLE, A.M., M.D. Sixth edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company.

The fourth edition of this now familiar work was reviewed in the issue of the JOURNAL for August 11, 1910 (vol. clxiii, p. 263); and the fifth edition in the issue for September 26, 1912 (vol. clxvii, p. 439). This sixth edition has been enlarged twenty-seven pages by minor additions and by the incorporation of a new chapter on the hygiene of infancy. The ten contributing authors remain the same as heretofore. The number of illustrations is increased from 131 to 138. The book maintains its former standard of excellence and there is nothing to add to the opinion of it expressed in our previous review.

Sleep and Sleeplessness. By ADDINGTON H. BRUCE, A.M. Boston: Little Brown & Co. 1915.

This monograph in the "Mind and Health Series" edited by the author, presents a study of the causes, nature and phenomena of sleep from the standpoint of the modern psychologist. The subject of dreams and the supernatural is carefully considered, together with other disorders of sleep and the causes and treatment of insomnia. The book aims to be not merely a scientific presentation but a work of practical helpfulness to the reader, and should thus be

of interest to the intelligent non-professional person in his effort, through correction of disordered sleep phenomena to arrive at a healthier, happier and more efficient life.

The Nursing and Care of the Nervous and the Insane. By CHARLES K. MILLS, M.D., Professor of Neurology in the University of Pennsylvania. Third edition revised by the author, assisted by N. S. YAWGER, M.D., Instructor in Neurology in the University of Pennsylvania. Philadelphia and London: J. B. Lippincott and Company. 1915.

This revised third edition of a standard manual on the nursing of neurologic and psychiatric patients aims to bring the original to date on the basis of newer developments in the knowledge of epilepsy and various of the mental diseases, and in accordance with more recent methods in non-restraint. The volume contains also useful anatomic and physiologic data, and is illustrated by several new charts and diagrams of electric apparatus. The motor point plates are from Dr. Cohn's work on electro-diagnosis and therapeutics. Instruction regarding hydrotherapy is not included in this work. Like the original, this edition is based on the substance of the author's teaching in the training school for nurses at the Philadelphia Hospital and at the Woman's Hospital of Philadelphia. It should continue to serve its useful purpose as a text-book of special nursing.

A Text-book for Midwives. By JOHN S. FAIRBAIRN, M.A., B.M., B.Ch. (Oxon.), F.R.C.P. (Lond.), F.R.C.S. (Eng.). With 3 plates and 104 illustrations, 5 in color. London: Henry Frowde and Hodder and Stoughton. 1914.

This text-book for midwives is in reality a text-book on obstetrics by an eminent British obstetrician. Assuming the midwife to be a desideratum in civilization, it could earnestly be hoped, though hardly expected, that she should live up to the knowledge and teaching of this admirable monograph. In European countries the midwife is probably a permanently integral part of the medical and social structure of the community. But in America the midwife is an anomaly and an anachronism; and though she has been introduced by and among the immigrants of our alien population, it is earnestly to be desired that she should not become an established factor in our professional and racial development. The existence of the midwife concomitantly with the physician involves the recognition of a dual standard which is incompatible with the dignity of the profession and the welfare of the public. Dr. Fairbairn's well written work in the series of Oxford medical publications could well be employed as an elementary text-book in medical schools, but as a text-book

for midwives it should have no field for use in this country.

A Manual of the Diseases of Infants and Children. By JOHN RUIERII, M.D., Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. Fourth edition. Illustrated. pp. 552. W. B. Saunders Company. 1914.

This fourth edition of a standard manual of pediatrics contains numerous minor changes from the original, with the addition of an article on pellagra in children, a new chapter on drug eruptions, a full account of the Binet-Simon test for the mentality of children and description of the use of the Soy bean and various newer methods in infant feeding. The book is well illustrated with 176 text figures and should continue its valuable service as a text-book for medical students and others.

Studies from the Rockefeller Institute for Medical Research. Vol. XX. New York: The Rockefeller Institute for Medical Research. 1915.

This volume, like its predecessors, consists of reprints of articles recently published as the result of investigations at the Rockefeller Institute. The present series consists of fifty-five papers, in English and German, in the fields of pathology, bacteriology, physiology, pharmacology, chemistry, biology and clinical medicine. Particularly to be noted are the studies of Flexner and others on epidemic poliomyelitis; of Noguchi, on the cultivation of the so-called trachoma bodies; of Rous and others on chicken tumors; of Van Slyke, on the fate of protein digestive products in the body; of Loeb and Lloyd, on artificial pathenogenesis. The volume continues the important body of contributions made by the Rockefeller Institute to the progress of medical science.

The Ninth Report of the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis. Philadelphia, Pa., 1915.

This volume is made up of reprints of articles published in various medical journals on the general subject of tuberculosis. It includes articles by Dr. Paul A. Lewis and others on Experimental Pulmonary Tuberculosis in the Dog, Experimental Tuberculosis of the Cornea, The Function of the Spleen in the Experimental Infection of Albino Mice with *Bacillus Tuberculosis*, and the Iodine Content of Tuberculous Tissues. Dr. H. R. M. Landis writes on The Medical Aspects of Pulmonary Surgery, Tuberculosis and the Public Health, The Health Aspects of the Clothing Industry and of the Pottery Industry, and The Diagnosis of Tuberculosis in

Early Life. Dr. George Ketterolf writes on The Larynx in One Hundred Cases Dying of Pulmonary Tuberculosis.

Aside from its intrinsic worth, the volume is interesting as a record of the scientific and useful work which this institution is accomplishing.

Factors Affecting the Health of Garment Makers. By H. R. M. LANDIS, M.D., and JANICE S. REED. Fifth Report of the Henry Phipps Institute for the Study and Prevention of Tuberculosis. Philadelphia, Pa. 1915.

Dr. Landis records the results of his investigations of health among garment workers under the following chapters: Rise of the Problem, Condition of Factories Studied, Racial Characteristics, Physical Condition of Employees, Physical Ailments as Related to Age and Trade Processes, Home Environment, Habits of the Workers, Wages and Trade Life as Related to Factory Conditions, Tuberculosis, Fatigue, Eye Conditions Encountered among "Pressers," and concludes with a general summary and recommendations. The information which the book contains is carefully and systematically arranged and clearly stated. As a record of conditions to be encountered in social and public health service, it should prove a valuable addition to the already existing literature on this subject of industrial hygiene. The volume contains a number of photographs taken of typical conditions in factories as the author found them, and a large number of tables and charts.

A Text-Book of the Practice of Medicine. For Students and Practitioners. By HOBART AMORY HARE, B.Sc., M.D. Third edition, revised and enlarged. Imperial octavo, 969 pages with 142 engravings and 16 plates in colors and monochrome. Philadelphia and New York: Lea and Febiger. 1915.

Dr. Hare has made very extensive changes in his third edition and has given us essentially a new book based on the general outlines of his previous edition. He has adhered to his original purpose of making the book reflect his personal views wherever possible. For example—in his discussion of the treatment of typhoid fever he outlines his own management of the diet and makes no reference whatsoever to the use of the liberal diet originally advocated by Shattuck, and carried to the extent of forced feeding by Coleman. References to the literature are not infrequent, but do not comprise a feature of any importance in the book. On the whole, like its predecessors, this edition is a sound exposition of the practice of medicine, based chiefly on the writer's wide experience in hospital and private practice. A very complete index is a valuable feature.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, JULY 29, 1915

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief*.
GEORGE G. SMITH, M.D., *Assistant Editor*.
WALTER L. BERRAGE, M.D., *For the Massachusetts Medical Society*.
FREDERICK T. LORD, M.D., *For the Massachusetts Medical Society*.

COMMITTEE OF CONSULTING EDITORS.

WALTER B. CANNON, M.D. ALLAN J. McLAUGHLIN, M.D.
HARVEY CUSHING, M.D. ROBERT B. OSGOOD, M.D.
DAVID L. EOSALL, M.D. MILTON J. ROSENAC, M.D.
REID HUNT, M.D. EDWARD C. STREETER, M.D.
ROGER I. LEE, M.D. E. W. TAYLOR, M.D.

ADVISORY COMMITTEE.

EDWARD C. STREETER, M.D., *Boston, Chairman*.
WALTER P. BOWERS, M.D., *Clinton*.
HOMER GAGE, M.D., *Worcester*.
JOEL E. GOLDTHWAIT, M.D., *Boston*.
LYMAN A. JONES, M.D., *North Adams*.
HUGH WILLIAMS, M.D., *Boston*.
ALFRED WORCESTER, M.D., *Waltham*.
ROBERT B. OSGOOD, M.D., *Boston, Secretary*.

ERNEST GREGORY, *Manager*. W. M. LEONARD, *Consulting Manager*.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty P. M.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager*.

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

GROWTH AND DISTRIBUTION OF POPULATION.

THE recently issued unofficial preliminary figures of the 1915 decennial census of Massachusetts present interesting data with reference to the population of this State. This census, which was taken as of April 1, 1915, shows a net increase of approximately 8.3% in the population of Massachusetts since the United States census of 1910. During the quinquennium for 1905-1910 the increase was 12.1%, and from 1900 to 1905 only 7.1%. The total population of the state is now 3,646,768. Massachusetts is now the sixth state in population, being exceeded by New York, Pennsylvania, Illinois, Ohio and Texas.

The population of Boston is stated as 725,823 as compared with 686,000 in 1910 (including Hyde Park), a gain of 39,823, approximately 5.8%. It had been estimated by census officials at Washington that the population of Boston on April 15 should be 733,802. Failure to reach

this expected figure leaves Boston still the fifth city in size in the United States.

In Massachusetts there are thirty-five cities and their approximate total population is now 2,537,949, about 69.3% of the total population of the State. In 1910 these cities contained 69.7% of the total population, indicating a slight, though very slight, tendency toward decentralization during the past quinquennium. The population of the metropolitan district known as Greater Boston is reckoned as 1,556,982, as against 1,423,429 in 1910. This metropolitan district includes 38 communities in addition to Boston. Of the cities outside Greater Boston only two, Salem and Gloucester, have decreased in population and these but slightly. The greatest gain in population was 33% in Chelsea, representing the rehabilitation of the city following its disastrous conflagration. A similar rehabilitation may doubtless be expected hereafter in Salem. Of the towns in the Commonwealth, over 70 show a decrease of population during the past quinquennium.

There has been an increase of population in every county of the State. This increase was greatest in Suffolk County, with Middlesex and Hampden ranking second and third. In Barnstable, Dukes and Nantucket Counties the increase has been but a few hundred. The distribution of population by counties in 1915 and 1910 is shown in the following table:—

	1915	1910
Barnstable	28,578	27,542
Berkshire	114,162	105,259
Bristol	344,490	318,573
Dukes	4,878	4,504
Essex	459,868	436,477
Franklin	48,172	43,600
Hampden	260,424	231,369
Hampshire	69,164	63,327
Middlesex	724,974	669,915
Nantucket	3,153	2,962
Norfolk	200,765	187,506
Plymouth	155,804	145,837
Suffolk	806,265	731,388
Worcester	426,131	399,657

Totals for the State, 3,646,768 3,366,416

In his statement accompanying the publication of these figures Mr. Charles F. Gettemy, director of the Massachusetts Bureau of Statistics, speaks particularly of the relation existing between immigration and the growth of population.

"The most obvious reason for the slowing down in the rate of increase during the latter half of the decade 1905-1915 is found in the recent notable decrease in immigration, which began even before the outbreak of the European War. For the United States fiscal year ending

June 30, 1907, immigration reached high-water mark, both in the number admitted to the United States and in the number destined for Massachusetts, a condition visibly reflected in the census figures for 1910. What the number will be for the year ending June 30, 1915, we do not yet know, but some idea of the shrinkage in population growth during the past year in Massachusetts alone may be obtained from the fact that during the eight-month period from the outbreak of the war, Aug. 1, 1914, to April 1, 1915, when the census was taken, the net increase in the population of the state from immigration (assuming that aliens giving their destination as Massachusetts, actually settled here), was, according to the reports of the United States Bureau of Immigration, 4430, as against 44,496 during the corresponding eight-month period of the preceding year. Immigration as affecting Massachusetts, however, began to show a perceptible decrease even before the outbreak of the war, for during the year ending June 30, 1914, the number giving their destination as Massachusetts was 8000 less than during the preceding year."

For some time it has been a matter of observation, and, among the thoughtful, of concern, that, although the population in this country has been steadily growing, this growth has been due largely to immigration and to the prolific fertility of recent immigrant families rather than to increase in the older native stock. In fact, the declining birth-rate among older American families stands already next to that of France, and is only slightly surpassed by that of Great Britain. Of the foreign white stock in the United States in 1910, the largest group was that of the English and Celtic, who numbered 10,037,420, representing 12.3% of the total white population of the United States in that year. The German group stood second, numbering 8,817,271, or 10.8%. The Italian group stood third, with 2,151,422, or 2.6%; the Polish group fourth, with 1,707,640, or 2.1%; and the Hebrew fifth, with 1,676,762, or 2%. Of the remaining persons of foreign white stock the majority were of various Slavic races. These data are based on a bulletin of the United States Census Bureau issued in May, 1914.

All these persons of foreign white stock constitute nearly 40% of the total white population of the country, and the remaining 60% a rapidly increasing proportion is made up of the first and second generations of the children of alien immigrants.

The relative proportion of the sexes in different parts of the country presents facts of interest. In the United States as a whole there

are 2,692,288 more men than women. This excess is determined chiefly by the population of the Western states. In the Pacific states the ratio of males to females is 129.5 to 100, and in the mountain states 127.9 to 100. In Massachusetts there are 55,920 more women than men. Rhode Island has an excess of 1,982 women. The only other states in which women predominate are Maryland and North and South Carolina. In Boston there are 11,171 more women than men, and in Philadelphia 28,082 more women. In New York, Chicago, St. Louis, Minneapolis and Pittsburgh, there is a very slight excess of men. Among the inhabitants of all the large cities in the United States there is an excess of 368,979 men over women, whereas in the rural districts there is an excess of 2,323,309 men.

These phenomena of population and their fluctuations perhaps derive their chief interest for physicians from the suggestions which they afford of the probable racial future of this country with the future development of the various ethnic groups of which its population is composed.

THE MORPHOLOGY OF THE CORPUS STRIATUM.

IN the issue of the *JOURNAL* for March 18, 1915, we published an item largely quoted from the work of Dr. S. A. K. Wilson in the *Lancet* and in *Brain*, on the function of the corpus striatum. Dr. Wilson concluded that the corpus striatum exercises a fairly definite function and that it is subject to a degenerative disease process clinically evidenced by a fairly definite train of symptoms known as the lenticular syndrome.

In the issue of the *Journal of Nervous and Mental Diseases* for June, 1915, Dr. James H. Lloyd approaches the same subject from the somewhat different standpoint of morphology. The corpus striatum, he points out, is, from an evolutionary point of view, one of the oldest portions of the mammalian brain. "It was, in fact, the whole brain in the arthropods, being known today as the supra-esophageal ganglion, and it continued to do duty as practically the whole fore-brain in the earliest vertebrates up to and including the fishes." Our knowledge of the morphology of the corpus striatum rests largely on the work of Gaskell (*The Origin of Vertebrates*, 1908):—

"In his treatise on the origin of the vertebrates Gaskell undertakes to establish the thesis that the vertebrates were developed from the arthropods, and that the cerebrospinal axis of the vertebrates was originally developed around and including the gastrointestinal tract of this lower form. If you will stop to reflect a moment, you will recall that in the arthropods, which include the crabs and the spiders, as well as in still lower forms, such as the insects and the segmental worms, the nervous system lies ventrad of the gastro-intestinal tract. It consists of a chain of ganglia lying beneath the creature's ventral surface; whereas in the vertebrates just the opposite is true, for in them the cerebrospinal system is located dorsad of the stomach and intestine. For a long time this was a stumbling block to evolutionists, for the problem stared them constantly in the face how the vertebrates ever succeeded in getting their nervous system on top of their bellies. The evolutionists resorted to all sorts of expedients to explain this apparently inexplicable thing; and such an eminent morphologist as Owen even proclaimed his belief that before the arthropod could have developed into a vertebrate, the creature must have turned over on its back."

As a matter of fact it appears that the nervous system of the vertebrate was evolved by building up nervous tissue around the old gastro-intestinal tube of the arthropod. The infundibulum thus represents the old esophagus, the pineal gland is the median eye, the corpus striatum the supra-esophageal ganglion, the cerebral ventricles represent the arthropod's stomach, and the spinal canal its intestine. Lloyd, therefore, regards the corpus striatum largely as a vestigial organ and doubts whether it continues in the human brain to exercise any functions whatever. There is little or no histologic evidence of any direct connection between the cortex and the corpus striatum. He is inclined, therefore, to doubt the clinical validity of the lenticular syndrome as a disease entity. Even Wilson admits that "there is no vestige of evidence that in man the corpus striatum is capable of assuming a long lost function and of acting vicariously for the motor pallium." Lloyd believes that the symptoms caused by lesions of the lenticula are merely symptoms derived from various affections of the internal capsule and that the lenticula has no other relation to the capsule than contiguity and common blood supply. He does not regard the corpus striatum as a coordinating center for speech, since morphologically and phylogenetically it could have no such function.

PEDIATRICS IN BOSTON.

THE June issue of the *Archives of Pediatrics* is published as a special Boston number and consists of seven original articles by pediatric members of the profession from this city. The first article, by Dr. John L. Morse, deals with Boston as a pediatric center and describes particularly the pediatric clinical facilities of this city and the opportunities of instruction offered by the department of pediatrics in the Harvard Medical School. The second article, by Dr. Maynard Ladd, contains essentially the same material on the subject of homogenized olive oil and fat-free milk mixtures, in cases of difficult feeding, which he presented before the New England Pediatric Society in Boston on Feb. 26, 1915, and which was published in the issue of the JOURNAL for July 1. The third article, by Dr. Charles H. Dunn and Dr. William W. Howell, presents a discussion of the diagnosis and treatment of pyloric stenosis and pylorospasm, based upon the experience of the Infants' Hospital. The fourth article, by Dr. Richard M. Smith and Dr. Stanley Cobb is a clinical and pathological study of one hundred infants, being a correlation of the data of two summers' work on the Boston Floating Hospital. These data are summarized under the headings of the gastro-intestinal tract, urine and kidney, tuberculosis, lymph nodes, fatty livers, lungs and size of the stomach. The fifth article, by Dr. Fritz B. Talbot, is a study of the energy metabolism of an infant with congenital absence of the cerebral hemispheres.

In the sixth paper Dr. Philip H. Sylvester and Dr. Freeman H. Hibben present a clinical and laboratory study of the relation of the gas bacillus to infective diarrhea and other digestive disturbances in childhood. They find that the gas bacillus is not a normal constituent of the human infantile intestinal flora, but that its pathogenicity is apparently demonstrable in certain cases of infectious diarrhea, fat intolerance and chronic intestinal indigestion. They believe that the dietary treatment by means of unpasteurized fat-free, lactic acid milk, which imposes conditions unfavorable to the growth and activity of the gas bacillus, is rational, safe and more immediately effective than any other treatment hitherto advocated.

In the seventh paper Dr. Joseph I. Grover records a study of measurements of a number of normal children, especially of the leg and arm, and suggests some interesting deductions and

practical possibilities. By graphic and tabular record and comparison he finds that the circumference of the head and chest bear a much more accurate relation to the weight than to the age of the individual, whereas the arms and legs grow in a definite relation to the increase in height. This growth bears a closer relation to the height than does percentage of the height to the age. Age, therefore, he concludes, is a poorer basis for the comparison of any dimensions than are weight and height, since development and age are not constantly parallel.

This issue of the *Archives of Pediatrics* thus presents a variety of contributions illustrating the range of the clinical and laboratory material in pediatrics available in Boston; and it is a pleasure to acknowledge to the editors their courtesy to this city and its profession in the preparation and publication of this special number.

FIRSTBORN CHILDREN AND SIZE OF FAMILIES.

In the July number of the *Journal of Heredity*, the official organ of the American Genetic Association, is an article by Professor Karl Pearson of the University of London, presenting the statistics of several thousand cases analyzed to determine the physical and mental quantities of firstborn as compared with later children. From this study he reaches the conclusion that the firstborn are physically and mentally inferior and have a poorer resistance to various infections, especially tuberculosis. These statistics, it may be mentioned, have been borne out by a similar study recently made by Mr. John H. Chase among students at Amherst College.

Professor Pearson further finds that there is an abnormally high percentage of firstborn children among the feeble-minded, insane, epileptic and criminal. It should be remembered, however, that this fact, like the higher percentage of still births among firstborn, may be accounted for partly by dystocia, partly by the predilection of congenital lues for first children. Mr. Chase's figures refer chiefly to physical vigor as evidenced by gymnastic strength tests, which represent probably the progressively increasing size often observed in the successive children of a family. For various reasons, however, it does appear that firstborn children are likely to be in various ways inferior to their later brothers and sisters.

The important and significant practical conclusion from these observations is, of course, the extreme undesirability of the limitation of families to one or two children. If the normal family be held to consist of five children, the inferior firstborn may often be the ones who will subsequently perish in the struggle for existence; and if they survive they constitute only a fifth of the population where their inferiority is of diminished importance. With families consisting of only one or two children, however, the firstborn will ultimately come to constitute a half or more of the population, with the result of racial decline not only in numbers, but in physical and, perhaps, mental vigor. As a matter of fact there is contemporary evidence of the probable truth of this conclusion in the phenomena of greater physical efficiency and vigor observed among the more prolific as compared with the less prolific European races.

ROCKY MOUNTAIN SPOTTED FEVER.

In another column of this issue of the *JOURNAL* we publish a brief clinical summary by Dr. Pope of Nevada of the present knowledge of Rocky Mountain spotted fever, that striking typhoidal disease of insect transmission. This disease has been for many years endemic in certain portions of Montana, Idaho, Nevada and Oregon, and recently, as noted in the weekly bulletins of the United States Public Health Service, it has made its appearance in Washington. Five cases of the disease were reported in Washington during May of this year, in Lincoln County, and on July 6, one case in Douglas County. During June there were five cases with four deaths in the Bitter Root Valley, Montana; and from March 1 to June 1 there were 206 cases with eight deaths in the southern part of Idaho. The disease is serious, usually with a high mortality, and its treatment, until some specific be discovered, is symptomatic and prophylactic. By way of prevention, the most effective method is dipping the sheep to destroy the ticks which, in springtime, infest their fleece, for although the tick infests other animals, the sheep seems to be the principal host. The development of the knowledge of this disease is an important achievement to the credit of American scientific medical research and is owed chiefly to Dr. Rucker of the United States Public Health Service and to Dr. Rickets, who

subsequently lost his life by infection with typhus fever which he was studying in Mexico. The hope of ultimate eradication of spotted fever, as of other diseases dependent for their transmission upon intermediate insect carriers, rests upon the possibility of exterminating this carrier and isolating all active cases of the disease.

MEDICAL NOTES.

THE WEEK'S MORTALITY IN NEW YORK.—Figures prepared by the Department of Health show that during the past week 1376 deaths were reported in the Greater City of New York, an increase of 90 over the number reported during the corresponding week of last year. Forty-two of these are accounted for by the increased population; the other 38 to the virulence of certain diseases, particularly measles, lobar and bronchial pneumonia.

Bright's disease showed an increase over the corresponding week of last year for the first time in several weeks. Nor was this increase offset by a saving of lives from chronic heart disease.

Despite the warm weather that prevailed during the latter part of last week, the death rate from diarrheal diseases was decidedly lower than during the corresponding week of last year.

The increase in the number of deaths last week was evenly distributed amongst all age periods, the group under five years showing the largest proportion, in which group there was an increase of 43 deaths. The group under 1 year of age escaped with a small increase of 7 deaths.

The death rate for the first 29 weeks of 1915 is 13.94, as compared with 14.42 for the corresponding period of last year.

FATALITY OF FOOT AND MOUTH DISEASE.—A report issued by the Pennsylvania Live Stock Sanitary Board on July 14 states that during the outbreak of foot and mouth disease last winter and spring, over 15,000 cattle and 13,000 swine were destroyed in that commonwealth. The cost of thus eradicating the disease in Pennsylvania was \$1,350,000, of which the United States Government pays one-half.

ESTABLISHMENT OF KEEN RESEARCH FELLOWSHIP.—Professor W. W. Keen has established the Corinna Borden Keen Research Fellowship in the Jefferson Medical College, the income from which now amounts to \$1000. The gift provides that the recipient of the Fellowship shall spend at least one year in Europe, America or elsewhere (wherever he can obtain the best facilities for research in the line of work he shall select, after consultation with the Faculty) and that he shall publish at least one paper embodying the results of his work as the "Corinna Borden

Keen Research Fellow of The Jefferson Medical College." Applications stating the line of investigation which the candidate desires to follow, shall be forwarded to Dr. Ross V. Patterson, Sub-Dean, Jefferson Medical College, Philadelphia, Pa.

EGYPTIAN VITAL STATISTICS.—The Egyptian government has recently published the vital statistics of its principal towns, governorates and provinces for the year 1914. "This report records 76,322 births (not including 2744 stillbirths) and 58,641 deaths. The birth rate is slightly below that of 1913—44.6 as against 45.1—but the natural increase is somewhat greater, for the death rate has fallen from 35.2 to 34.3. Typhus is responsible for the largest number of deaths attributed to infectious diseases, the total number of cases being 9350, the provinces of Daqahalia and Beheira each returning more than two thousand, with 2531 deaths. Smallpox is represented by 6788 cases and 1568 deaths, and measles produced 5045 cases with 2272 deaths. Only 219 cases of plague were reported, 50 of these from Port Said. Typhoid was responsible for 1966 cases and 612 deaths. The estimated population (July 1, 1914) was 1,710,857."

PREVALENCE OF PELLAGRA, PLAGUE, POLIO-MYELITIS, SMALLPOX AND TYPHOID.—The weekly report of the United States Public Health Service for July 16 notes that during the week ended June 26 there were six deaths of pellagra in Charleston, S. C., and three cases of poliomyelitis with one death in New York City. During the same week there were twenty-one cases of typhoid fever with one death in New York City and twenty cases and one death in Charleston, S. C. There were also two deaths from virulent small-pox at El Paso, Texas, and two cases with one death at New Orleans, La. On July 7 a plague infected squirrel was found in California and on July 14 a plague infected rat in New Orleans.

INTESTINAL INFECTION AND SEWAGE DISPOSAL.—In a recent issue of the *Public Health Reports*, Dr. C. W. Stiles records the results of an investigation of the prevalence of intestinal infections in children as influenced by sewage disposal. He has taken for investigation a town in the coastal area of a Gulf-Atlantic state with a total population of 30,000, the whites outnumbering the negroes. The city was but partly sewered. Twenty-five hundred white children and 1350 negroes were examined for worm parasites, the sexes in each division being about equal.

"The parasites, which could be acquired only through swallowing them and whose origin is human wastes, were found in 20% of the white girls, 49% of the negro girls, 34% of the white

boys and 47% of the negro boys. Throughout the tabulation the white girls have everywhere low rates, but even in the houses having sewer connections the rate of infection is about 19%. Those infections that were probably through the skin range from 20 to 30% in the white children in unsewered homes, 6 to 10% in sewerd houses, while for negro girls the rate is below 5% and for boys less than 2%. These last figures, however, rest on comparatively small numbers.

"The conclusions of Professor Stiles from his investigation are that there is a vast amount of unconscious coprophagia in human beings, that it is a very variable amount even in the same community, and that the outhouse in thickly settled communities is a distinct danger."

MEDICAL ASPECTS OF GASTRIC CARCINOMA.—In connection with the cancer number of the JOURNAL on July 15 we are glad to call attention to an article on the medical aspects of gastric carcinoma by Dr. Joseph C. Bloodgood of Baltimore, appearing in the *Journal of the American Medical Association* on June 19. The observations noted in this article suggest that the true aspect of the result of surgical intervention in cancer of the stomach points with particular fatality to the fruitlessness of delayed treatment. In the series of 184 cases upon which Dr. Bloodgood's paper is based, 74% were already inoperable when first seen. The significance of this fact is obvious and should emphasize to the profession, as well as to the laity, the cardinal importance of the earliest investigation of obscure gastric symptoms in order to make surgical aid for incipient gastric carcinoma of practical avail.

VALUE OF CHAULMOOGRA OIL IN LEPROSY.—In the issue of the JOURNAL for July 8 we commented editorially on the use of chaulmoogra oil at Molokai in the treatment of leprosy. This oil is made from the seeds of takatogenos kurzii and is combined with camphor and resorcin for hypodermic administration.

In the leper colony at Cnlion, Philippine Islands, there were at the close of 1912, 2615 lepers. The report of the Philippine Commission for this year spoke as follows of the use of chaulmoogra oil for their treatment.

"Chaulmoogra oil, when taken continually over long periods of time, continues to prove most useful in treating the disease, and results in some apparent cures. Unfortunately, most persons experience difficulty in taking it.

"Twelve colonists who had been treated with chaulmoogra oil were sent to Manila apparently cured of leprosy, but it was subsequently necessary to return two of them who had suffered relapse."

In March, 1914, the *Lancet* recorded the discharge by Dr. Victor G. Heiser from the San Lazaro Hospital for Lepers at Manila of two

patients who, after this treatment, had been free from manifestations of the disease for two years. A report from Manila on July 15 states that Dr. Mercado, a local Filipino physician has reported 80 cases of leprosy treated with chaulmoogra oil of which 23 have been discharged as cured.

Despite the apparently favorable character of these reports the specific curative value of chaulmoogra oil must await further and longer experimental trial and demonstration.

MEDICAL BROTHERHOOD FOR INTERNATIONAL MORALITY.—In the issue of *Science* for April 9, 1915, was published an address by Dr. S. J. Meltzer of the Rockefeller Institute for Medical Research on "The Deplorable Contrast between Intrnational and International Ethics and the Mission of Medical Science and Medical Men." On the basis of the theories advanced in this address Dr. Meltzer has recently issued an appeal to physicians in the United States to join in the creation of a medical brotherhood for the furthering of international morality. To this end there has been formed a committee of 120 well known physicians and it is hoped that financial support may be obtained from the Carnegie Endowment for International Peace.

GREAT INCREASE IN FATAL AUTOMOBILE ACCIDENTS IN NEW YORK CITY.—Figures prepared by the Bureau of Records of the Department of Health show that during June, 1913, 34 persons were killed upon the streets of New York City by automobiles, an increase of 70% over the number of similar accidents that occurred during June, 1914. This increase is not at all exceptional; it is, on the contrary, only a reflection of the steady increase in this class of accidents that has been going on for several years, as is borne out by the following table:—

	Manhattan.	The Bronx.	Brooklyn.	Queens.	Richmond.	City.
1910.....	63	13	25	7	3	111
1911.....	77	8	38	3	2	128
1912.....	120	14	44	9	1	188
1913.....	173	33	64	16	7	293
1914.....	168	30	86	22	4	310
1915 (6 months)...	104	14	24	8	2	152

The second half of the year always shows higher figures than the first half. The total number of accidents will therefore be considerably higher this year than in 1914.

During the first six months of 1915, 152 lives were needlessly sacrificed. Aside from the humanitarian side of the question, this loss of life entailed an immense economic loss, which has swollen to a still greater total by the numbers disabled temporarily or permanently. A conservative estimate is that one person in ten injured dies. Assuming this ratio to have held

good in this city during the six months of 1915, there were 1520 persons injured by automobiles.

According to the Health Department the cause of the increase is to be found in the increased number of motor cars in the city streets, and it calls on the people of this city immediately to attempt to secure uniform standards for all who operate motor vehicles, and to demand more stringent enforcement of existing regulations.

The department points out that the control of an automobile in the streets of New York is not a task for a child, an untrained amateur, a neurasthenic, an excitable person or a weakling. In the hands of such persons, a motor vehicle is an engine of death. It is the clear duty of the authorities, then, to see that the competency and trustworthiness of every would-be operator is satisfactorily established. How does the legislature perform this duty? By the enactment of a statute which requires no test of an owner's capacity, and which expressly prohibits any local authority from enacting supplementary protective regulations.

Under the highways law of the state of New York, any owner or any member of the family of an owner is permitted to drive a motor car. The question of mental or physical capacity does not enter; and yet there is not the slightest doubt about the risk involved.

In commenting on the increase in deaths from automobile accidents, Commissioner Goldwater said: "The Department of Health is helpless in the matter. What we need is legislation equal in effectiveness, equal in common sense and in humanity to that of other states. If the legislature is unwilling to enact protective regulations applicable throughout the state, then we ask that the hands of the Board of Aldermen and the Board of Health be untied, so that there may be adopted in this city, at least, an ordinance which will compel those who desire to operate motor vehicles on the streets of the city to submit to an adequate test of fitness as a condition precedent to the obtaining of a license or permit. We call upon the people of the city for their support in this altogether reasonable demand, which will be renewed with emphasis when the next legislature convenes."

PREVENTIVE MEDICINE IN THE UNITED STATES

ARMY.—The latest annual report of the surgeon general gives a very gratifying account of the decline of disease rates in the United States Army for the year 1913. Smallpox and typhoid fever have been practically eradicated from the Army. The rate for malaria fell from 84.36 to 24.75. The admission rate for venereal disease for 1913 was 97.22. The rate for the previous year was 136.7, a decrease of about 30% in one year. A corresponding decrease for another year or two would bring the rate to about 40, that attained by the German army just prior to the outbreak of the war. In ten

years the rate of sickness from all causes fell from 1230 to 671, almost 50%. The death rate, however, has fallen but 30%. The number of men per 1000 excused from duty on account of illness now is less than half what it was ten years ago. Alcoholism in the army was at its worst in 1907. Since that time it has also fallen 50%.

ST. LOUIS EXPEDITION TO CENTRAL AMERICA.—On Monday of this week, July 26, there started from St. Louis, a scientific expedition from the St. Louis University to study tropical diseases in Central America. This expedition, which will proceed first to British Honduras, is in charge of Dr. Edward Nelson Tobey, instructor in tropical diseases at the University.

AMERICAN SURGICAL ASSOCIATION.—At the annual meeting of the American Surgical Association held in June, 1915, at Rochester, Minn., it was voted to hold the next session at Washington, D.C., in 1916. The following officers were elected for the ensuing year:

President, Dr. Robert G. Le Conte, Philadelphia; vice-presidents, Drs. Charles L. Gibson, New York City, and Archibald MacLaren, St. Paul; secretary, Dr. John H. Gibbon, Philadelphia; recorder, Dr. John F. Binnie, Kansas City, Mo.; and treasurer, Dr. Charles H. Peck, New York City.

ALCOHOL AND THE FRENCH BIRTHRATE.—Report from Paris on July 19 states that an investigation has recently been made by Charles Benoist into the causes of the progressive depopulation of France. For this purpose he selected the Canton of Crenelly, in the Arrondissement of Caen, where the decline of population has been particularly notable. He believes that he has found a definite connection between the decreasing birthrate and the consumption of alcohol, particularly of elder brandy which is distilled and drunk by the natives in great quantity. The custom of taking brandy in coffee probably leads to a larger consumption of the former than would otherwise be the case.

"Whether drink may be considered the cause of the decrease in the birthrate or not, the progression of depopulation seems to have kept pace with the progression of alcoholism. Where the consumption of spirits was formerly a gallon and a half a year per capita, it is now more than three gallons, while the decreased birthrate traced back through many generations in the same families by Monsieur Benoist shows a decrease from an average of seven children a family in the nineteenth century to three in the twentieth."

In the department of Calvados which constitutes 1% of the population of France there are 4% of the total number of controlled distilleries in that country which in 1912 produced 170 gallons of pure alcohol, equivalent to 485

gallons of brandy, a rate of more than a gallon per capita. It is stated that in some communes the annual consumption of cider brandy approaches 10 gallons per capita.

ROCHESTER DENTAL DISPENSARY.—At a meeting on July 20 of the Rochester (N.Y.) Dental Society, there was announced a gift of \$300,000 from Mr. George Eastman for the erection in that city of a free dental dispensary.

EUROPEAN WAR NOTES.—Report from Washington, D.C., on July 17 states that as a result of the European War, American exports of medicine and surgical instruments have nearly doubled. It is estimated by the Bureau of Foreign and Domestic Commerce that during the year ended June 30, 1915, the exports of this class of goods amounted to \$35,074,000 in value as compared with a value of \$19,916,000 during the year ended June 30, 1914.

Report from New York states that Dr. F. H. Hodge of Knoxville, Tenn., reached this country on July 18, aboard the *Cymric* on his return from Liverpool. He stated that the maximum of typhus infection in Serbia was reached in March of this year when 48,000 cases were recorded. At present the number of cases is less than 1,000. Dr. Hodge is quoted also as saying that ten American Red Cross nurses have been transferred from Serbia to Malta where a military hospital has been established for the care of the wounded from the allied armies at the Dardanelles.

Report from Budapest by way of Geneva and Paris on July 16, states that during the week ended June 28 there were in Hungary 543 cases of Asiatic cholera with 281 deaths. Of these, 81 cases and 24 deaths were among soldiers.

It was announced in New York on July 19 that the American Red Cross is to establish an obstetric hospital in Serbia to be known as the Mabel Gronitch Hospital. It is expected that this institution will be in charge of Dr. Louise Taylor Jones of Washington, D. C., with Dr. Katherine H. Travis of New Britain, Conn., as her assistant.

In another column of this issue of the JOURNAL we publish an extensive statement of the rise in price of drugs since the outbreak of the European war. On July 23 it was further announced that antipyrin has advanced in cost from \$9.50 to \$13 a pound and caffeine from \$5 to \$8 a pound since July 1. On June 3, 1915, antipyrin was selling at \$6.50 and caffeine at \$4 a pound.

On July 24 the total of the New England Belgian relief fund amounted to \$265,775.10; and that of the Polish fund to \$48,941.01.

BOSTON AND NEW ENGLAND.

RECORD ATTENDANCE AT MILK STATIONS.—The Boston Milk and Baby Hygiene Association reports that last week it cared for the largest number of babies in its history, the total number being 612, which was more than double the number of the previous week, 302.

OPEN AIR SCHOOL ON CASTLE ISLAND.—There has been opened at Fort Independence, Castle Island, an open air school attended by 125 pupils of three South Boston schools. It is maintained by the Association for Control of Tuberculosis, Instructive District Nursing Association and the Boston Dispensary. Miss Katherine French of Boston is in charge. The children are provided with a lunch and all the milk they can drink and are charged five cents a day to help defray expenses. Contributions for carrying on this important philanthropy may be sent to W. G. Wendell, treasurer, 60 State Street, Boston.

POLIOMYELITIS IN VERMONT.—The first well marked outbreak of poliomyelitis in Vermont occurred in the year 1894 when there were 126 cases at Rutland with 18 deaths. Since that time the disease has apparently become endemic in that state with occasional sporadic outbreaks of which the most extensive was that of 1913 when there were 200 cases. The cause of this recent development of poliomyelitis in a state hitherto apparently free from it is uncertain, but may probably be traced to some carrier who settled in Rutland and from whom the infection has since been spread, very possibly by insects.

WATER SUPPLY OF BOSTON AND VICINITY.—The Metropolitan Water Works, which supplies with water the cities of Boston, Chelsea, Everett, Malden, Medford, Melrose, Newton, Quincy and Somerville, and the towns of Arlington, Belmont, Lexington, Milton, Nahant, Revere, Stoneham, Swampscott, Watertown and Winthrop, a total population of 1,777,770, required for its maintenance during the past calendar year the sum of \$413,078.95. The quantity of water supplied to the Metropolitan Water District during this time was 107,036,100 gallons, an equivalent to 94 gallons for each person. This quantity was 3,188,400 gallons more than the average daily consumption of the preceding year.

ADAMS NERVINE ASYLUM.—The recently published thirty-eighth annual report of the Adams Nervine Asylum in Jamaica Plain, Mass., gives the following information regarding its affairs for the year ending May 1, 1915.

The number of patients under treatment during the year was 225 (51 men and 174 women). Of these, 40 (6 men and 34 women) were in the Asylum May 1, 1914, and 185 (45 men and 140 women) were admitted during the year. There were discharged as recovered, 10; relieved, 120;

not relieved, 44; declining treatment, 2. Two patients died, and 47 (14 men and 33 women) were remaining in the Asylum April 30, 1915. The daily average number of patients was 44 (men, 12; women, 32).

The average cost per week for each patient, including all payments charged to current expenses, was \$24.01.

The amount received from patients was about 38% of the expenses.

FOOT AND MOUTH DISEASE IN MASSACHUSETTS.—It is announced by the Massachusetts State Bureau of Animal Industry that this Commonwealth is now free from the epizootic of foot and mouth disease and that the quarantine imposed in November, 1914, is now removed except for the transportation of cattle to and from Watertown and Brighton. Farmers whose stock has been slaughtered have been urged by the Bureau to restock their barns in order that it may be decided whether or not the disease still lurks in the buildings. This is being done generally and no new outbreaks have yet been reported.

RETURN OF THE FIRST HARVARD SURGICAL UNIT.—A majority of the members of the first Harvard Surgical Unit have returned safely to the United States aboard the French steamship *Rochambeau* landing at New York on July 13. This unit sailed from New York on March 17 aboard the *Canopic* and since April 1 has been in charge of the University service in the American Ambulance Hospital at Neuilly, Paris. Dr. F. A. Collier, who went out with the unit, has joined an English unit for service in a British military hospital and Dr. George Benet has taken service in an Anglo-French Red Cross hospital near the firing line north of Compiègne.

DR. CREEL AS BOSTON HEALTH COMMISSIONER.—In the issue of the JOURNAL for May 13 we announced the acceptance by Dr. Richard H. Creel of the United States Public Health Service of an appointment as health commissioner of the city of Boston. In the issue of the JOURNAL for June 10 we published a further statement containing a letter from Dr. Creel in which he expressed the necessity of declining this appointment on account of his health. In the issue of the JOURNAL for July 1 we published another announcement of Dr. Creel's decision again to reconsider his action and to accept the appointment for one year beginning July 1, 1915. It now appears, according to report from Washington, D.C., on July 14, that Dr. Creel's health is not sufficiently good to permit his undertaking this work at present. Without definitely declining the appointment, therefore, he is to go on furlough for vacation after which a decision as to his acceptance will be definitely made.

Dr. Creel has recently been engaged in the work of plague prevention by extermination of

rats in New Orleans, since the outbreak of the disease in that city last summer. During this time there have been trapped and killed in New Orleans 396,151 rats of which 244 were found infected with bubonic plague. Of those infected 216 were Norway rats, who numbered 202,570 of the total number killed. The last human case of plague at New Orleans was reported on October 4, 1914.

MELROSE HOSPITAL TRAINING SCHOOL.—The annual graduation exercises of the Melrose Hospital Training School for Nurses were held at Melrose, Mass., on July 21. The principal addresses were made by Dr. Walter R. Bowser, secretary of the Massachusetts State Board of Registration of Nurses, and by Miss Mary Beard, director of the Boston Instructive District Nursing Association.

RECENT HOSPITAL BEQUESTS.—The will of the late William Bradford Weston of Milton, Mass., which was filed for probate on July 14 in the Norfolk Probate Court at Dedham, Mass., contains bequests of \$15,000 each to the New England Hospital for Women and Children, the Massachusetts General Hospital, the New England Peabody Home for Crippled Children, the Perkins Institution for the Blind and the Vincent Memorial Hospital. These legacies, however, do not come into effect until twenty years after the death of the longest lived of 31 personal beneficiaries named in the will for whom funds are held in trust. The will further establishes a trust fund of \$6000 to be held by the Massachusetts Hospital Insurance Company for the term of 100 years. At the end of this time the accumulated fund is to be divided into two parts of which one shall be used for the erection in Milton, Mass., of a small free fire-proof hospital to be known as the Weston Hospital. Sevent-eighths of the other part are to be used for the erection of a similar hospital at Duxbury, Mass.

The will of the late Mary J. Neas of Jamaica Plain, Mass., which has recently been filed for probate, contains bequests of \$500 each to the Boston Nursery for Blind Babies and to the Faulkner Hospital, Jamaica Plain.

Obituary

**RICHARD CLEMENT LUCAS, M.B., M.S.
(LOND.), F.R.C.S. (ENG.).**

MR. RICHARD CLEMENT LUCAS, who died on June 30 at Oakland, Midhurst, Sussex, England was born there in 1846. He studied medicine at Guy's Hospital and obtained the degree of M.B. from the University of London in 1871. He immediately became demonstrator and later lecturer in anatomy, and in 1875 was appointed assistant surgeon at Guy's Hospital. At the

same time he was developing a large and successful private surgical practice in London, devoting himself first to ophthalmic surgery, and later in particular to renal surgery. He was for a time vice-president of the Royal College of Surgeons of England and in 1911 delivered the Bradshaw lecture upon various problems in heredity. He was an occasional contributor to the columns of the *Lancet*. As a surgeon he was essentially an anatomist and in the teaching of anatomy he found, perhaps, his most enthusiastic activity. He is survived by two sons. The following vivid sketch of his personality by Sir Arbuthnot Lane appears in a recent issue of the *Lancet*.

"By the death of Richard Clement Lucas the profession loses an eminent surgeon and a remarkable man. His was a distinct personality which cannot be ignored when the surgery of the late Victorian era is under review, and his name will be always associated with the early development of renal surgery, in which subject he took a continued interest. He served Guy's Hospital for nearly half a century, and devoted an enormous amount of time and energy not only to his hospital duties but to the education of the students, in every one of whom he took a great personal interest. Quite a number of his colleagues owe their success in life to the stimulus which he applied to them by his interest and advice in the early stages of their careers. He used to ask the first year's men to meet him in order that he might discuss with them collectively and individually the best course for each to pursue in his work, and few who were present at one of those talks will forget the strong impression that he made upon the young student. Full of ambition himself, and indefatigable in work, he certainly possessed a wonderful power of inducing energy in others. In his prime he was a masterly operator—bold, rapid, and certain. Nothing pleased him more than a deep and extensive dissection in the neck, in which his dexterity and anatomical knowledge had full play. In his work he was always teaching the student, and the interest of his lectures was notably enhanced by the excellent lightning sketches with which he illustrated them. He wrote a large number of papers on anatomical and surgical subjects, in many of which he displayed remarkable originality."

Miscellany.

RISE IN THE PRICE OF DRUGS.

REPORT from New York on June 22 states that there has been a general rise in the price of a large number of drugs since June first of this year, chiefly on account of the disturbance of the market involved by the European War. The cost of quinine, for instance, has recently been

advanced 32 cents per pound. This drug now costs 30 cents per ounce in hundred ounce quantities and 35 cents per ounce for smaller amounts.

"English interests have purchased upwards of 350,000 ounces of quinine sulphate in the American markets in the past four months. This quinine has been utilized in combating malaria, coughs, colds and other maladies prevalent in the European war zone. It is understood that England as purchasing agent for the Allies has placed forward orders for the great bulk of the United States quinine production to the end of this year. One recent shipment of 25,000 ounces of quinine which was forwarded from New York to London on the steamer *Inkum* was lost through the torpedoing and sinking of that steamer on June fifth by a German submarine.

"Further reasons for the unabated strength now shown in quinine and all its minor salts lie in the fact that the shipments of cinchona bark from the Island of Java to Europe for the first five months of the current year have only amounted to 2,215,000 kilos, compared with 3,103,500 kilos in the corresponding five months last year and 2,781,200 kilos in 1913, and 2,311,500 kilos for the corresponding period in 1912. The shipments for the month of May were only 450,500 kilos against 612,000 kilos in May, 1914, 488,000 kilos in May, 1913, and 689,000 kilos in May 1912. It is thus clear that the shipments of basic material have been naturally curtailed and that this has not been the real reason for the sharp advance in prices for the salts at the London and Amsterdam salts auctions where a unit of 11½d is now generally being realized.

"There has also been a rise of 25 cents per pound in the price of opium which now costs \$7.25 per pound in cases, powdered opium being \$8.25 per pound.

"While ostensibly basing their advance asking figures for this narcotic on reports that the Turkish Government had imposed an embargo on all shipment of the gum from Turkish possessions, it was believed that the action of the importers was based more generally on the knowledge that customers will buy more readily on a rising than a declining market. The consensus of opinion among the trade is that the advance in this article is not warranted as the stock in the United States is now at the largest point in the history of the drug trade. It is also known that the necessity of observing all the requirements of the Harrison Anti-Narcotic Law as well as the supplementary state statutes of similar character has materially restricted the buying of this article."

"The history of the drug trade reveals no more astounding chapter than that which has been written the past few weeks. Fine medicinal as well as technical drugs and chemicals have advanced to a point where values are 500- to 5000-fold inflated. Speculators and second-hands are virtually reaping a harvest. Manufacturers are in a majority of incidences sold

out of certain wanted materials for periods ranging from six months to a year ahead. So far as imported goods are concerned, it is known that harvesting and manufacturing operations in leading French, German, Russian and English drug centers are either at a minimum or are practically suspended. The high record values prevailing in the domestic markets are justified to some extent, however, as export demand has also been in evidence and has reduced the spot supplies of most materials to negligible proportions. Exact statistics are not yet available, but it is known that during the first two months of the current year the total export of drugs, chemicals and medicines from the United States amounted in value to \$7,460,000 against \$3,986,000 in the same time in 1914, and \$4,157,000 in the corresponding two months of 1913.

While drug values in general have fluctuated in accordance with supply and demand considerations it is contended by some well known interests that present prices do not portray conditions prevailing. Epsom salts are a fair example of an article which is available in the United States in plenitude. Prices have, however, been jacked up to a basis of \$3 per hundred weight within the past three weeks against a price of \$1.75 per hundred weight on June 1. Caustic soda, an alkali product used generally in soap making, reflects the demand from Europe as well as the domestic explosive trades at its present high record figure of 3.25 (a 3.50 per cwt. Various factors have sold out their entire output of this material for months to come.

All quicksilver preparations have been subjected to further sharp advances and dealers are now offering them very sparingly. Santonine, the active principle of Levant wormseed, grown and manufactured in Russia, has undergone an advance of \$13.50 to \$23.50 per pound since June first, owing to the reports of a great shortage in this year's crop of the seed. Russian isinglass, utilized in clarifying beverages, has also advanced sharply and at its present level of \$6 per pound is no longer regarded as a commercial article.

A continued shortage of muriate of potash, utilized in manufacture of bicarbonate of potash, bichromate of potash, carbonate of potash, chlorate of potash, prussiates, saltpetre and a host of other technical chemical preparations, has sent prices for the preparations mentioned to still higher levels and values are now merely nominal, as holders ask whatever price their conscience dictates. A development of interest yesterday was the announcement by manufacturers of boric acid of a further advance of 34 cent per pound, making the revised figures for crystals and powdered 9 (a 10 cents per pound. A fresh advance of 1/2 cent per pound was also announced by manufacturers of borax which was held at 53 1/2 (a 6 cents per pound.

Report from New York on July 14 states that the prices of Norwegian cod liver oil have also

advanced to \$100 a barrel from \$45, an increase of \$55, or 122%.

"The sharp elevation of prices follows cable advices that the cod fishing season abroad closed with a reduction of 14,000,000 fish, or 21%, noted in the total catch as compared with a year ago. Cables also conveyed the information that Germany had bought heavily of the 1915-1916 output and that over 50% of the total production had been absorbed in this way. It is said that a group of European speculators have succeeded in obtaining control of all but a meagre proportion of the remaining stocks and that cod liver oil is destined for still higher prices.

"The market flight of cod liver oil does not find adequate justification in comparison of final fishing returns from Norway, the total output for the year just closed having been 66,800,000 fish, which yielded 45,620 barrels of refined oil as against 81,500,000 fish or 49,285 barrels of oil for the former season. The fundamental explanation lies in the abnormally heavy demand for Norwegian cod liver oil for German mechanical war requirements, chiefly as a lubricant in the various lines of motor service, the use being even extended to aeroplanes through the refining process eliminating the stearine. The medical application of the oil was also found especially beneficial in relieving the painful physical effects of extreme cold upon the German soldier.

"Prompted by the elevation of prices for the various brands of cod liver oil, including Holme's, Devoe's, Duval's, Dervell's and Isdahl's to \$100 per barrel, there have been sharp speculative operations in the New York market, and all lots available below \$75 per barrel have been snapped up. Evidence of the lightness of American stocks and the consequent restrictions in extensive speculation here are furnished in the record of our imports for the first six months of the current year, which amounted to only 1700 barrels as compared with 4200 barrels, 2800 barrels, and 3900 barrels for the corresponding periods of 1914, 1913 and 1912 respectively.

"Of the current production of 45,620 barrels, the Lofoten fishing, usually relied upon for the finest grades of refined oil, has contributed about 11,000 barrels from 16,000,000 fish as against 8200 barrels from 12,000,000 fish last year. Fishing operations in Norway were not only handicapped by loss through seizure and sinking of trawlers the past season, but stormy weather created difficulties hard to overcome.

Following this phenomenal rise of value in Norwegian oil there has been a rise of Newfoundland oil from \$40 to \$50 a barrel. This oil though not so refined in quality as that in Norway, will probably now be extensively employed as a substitute.

"There has been a marked improvement in Newfoundland's refining process during the past year or so and this has placed it on a better competitive basis with the Norwegian grades

The season in Newfoundland gets into headway with the close of the season in Norway, and possibilities of profit under existing prices should hasten operations, especially in view of the fact that England is expected to draw heavily on this year's yield."

It is also announced that the price of thymol has advanced from \$2.00 to \$12.00 a pound, an increase of 500%. "The advance is due to the scarcity of supplies and the active demand from manufacturers of antiseptic washes and dental preparations, who report considerable difficulty in securing sufficient thymol for their users, being forced to bid in competition with exporters who have been buying freely on orders from France and England.

"Germany has up to this time enjoyed a distinct monopoly in thymol manufacture. The article is produced from anjowan seed grown in India. Germany's requisitions on the anjowan seed production in 1914 were 6990 cwt., out of a total production of 9784 cwt., while in 1913 her takings were 19,055 cwt., out of a total production of 21,650 cwt., and in 1913 her takings aggregated 14,210 cwt., out of a total of 15,515 cwt., produced. Thus far this season Germany has taken over 6000 cwt. of the Indian anjowan seed production and the United Kingdom has only secured 382 cwt.

"It is impossible to estimate accurately what the production of thymol in Germany amounts to. It is reckoned, however, that the output of thymol from anjowan seed is about 14%, so if it is assumed that the whole of the seed shipped to Germany was used in the manufacture of the drug, the production in that country from Indian seed would amount to 177 cwt., in 1911-12, 238 cwt., in 1912-13, and 87 cwt., in 1913-14.

"As in the case of other drug and chemical products, the high prices for thymol have stimulated production in other parts of the world. A despatch from Bengal, India, says that a laboratory worker in the Bengal Chemical and Pharmaceutical Works has been the first to produce thymol. This despatch was contradicted, however, in advices from London which stated that thymol has been made in certain districts in India for the past sixty years. This despatch stated that the manufacture of the article had been discontinued when the low prices for the German product made it unprofitable some years ago, but that Indian interests had again commenced to manufacture it for their own requirements, and had shipped large quantities as well (one shipment of twenty tons being under way) to English firms."

All domestic manufactures of mercurial preparations have also advanced from three cents to eight cents a pound. "The great bulk of all quicksilver which has found its way from California to New York within the past few weeks has been taken by the Allies for manufacture of ultimate for percussion caps. Quicksilver values have again advanced for this reason, and little or any is now offered here at below \$100

and \$105 per flask of seventy-five pounds. Yesterday's action of domestic manufacturers brings quotations of soft mercurials in fifty-pound lots and over to a basis of 72 cents per pound for blue mass, 74 cents per pound for blue pills, 74 cents per pound for mercury and chalk, 90 cents per pound for mercurial ointment '1/2' and 80 cents per pound for blue ointment or mercurial ointment '1-3.' The new schedule on hard mercurials in fifty-pound lots is calomel, \$1.43; corrosive sublimate, powdered, \$1.30; corrosive sublimate, crystals, \$1.35; mercury bisulphate, \$1.21; red precipitate, \$1.56; red precipitate, powdered, \$1.66; white precipitate, \$1.66, and white precipitate powder, \$1.71."

The cost of potassium bromide has now risen to \$1.50 a pound.

These figures are of interest to physicians since they illustrate the effect upon the drug market of the disturbing economic conditions attending war. So far as possible in prescribing, physicians should endeavor in the interests of their patients to avoid those drugs whose prices have been most unduly advanced, employing equivalent substances wherever possible.

TREPHINING AMONG THE PERUVIAN INDIANS.

A RECENT issue of the *New York Times* calls attention to a detailed description by Dr. Joseph C. Thompson of the United States Navy Medical Corps of the methods of trephining practiced by the Peruvian Indians early in the Christian era. This description is based on a study of over 5000 pre-Columbian Indian skulls collected by Dr. Irdlicka, curator of the division of anthropology of the National Museum at Washington, D. C.:—

"These ancient Peruvian Indians observed that once in a while warriors who had received a serious injury of the head recovered instead of dying. In the course of time they learned that these recoveries were due to one of several causes.

"The skull, in the living subject, is very resilient, and it may have happened occasionally that when a piece of the skull wall was displaced or dented, thus compressing the brain, this offending fragment suddenly sprang back into place, thereby relieving the symptoms and affording the patient a chance to recover. Among primitive peoples some very curious ceremonial rites take place over the dying. These rites, at times, assume the character of a vigorous massage of the body, and they even tapped the head of the dying man with a baton. This latter action might readily result in a lucky repair of the broken skull.

"Then, again, after a warrior had lain unconscious for many days, the splintered and broken bits of bone might necrose and be sloughed off at

the bottom of an open sore. This also might have resulted in a recovery.

"When the medicine men had observed these phenomena a few times, their next logical step would be to attempt to assist nature in her processes of restoration. They did this by prying the displaced fragments into place and by digging out, often with their finger tips, splintered bits of bone. Another of their observations was that a wound with sharp, clean-cut edges would heal much more rapidly than one with a rough or jagged contour.

"The result of their observations was that they attempted to convert the rough, irregular gashes in the skull into smooth, clean-cut surgical wounds. This was usually done by scraping the edges of the break with the sharpened flints.

"They further advanced in the science of physical diagnosis to the point of observing that, now and then, a warrior died from a really small fracture of the skull. This led them to operate quickly, and some of the slender pieces of sharpened flint may have been used to raise the crushed portion of the skull, after an incision had been made."

Correspondence.

PRUDENTIAL HOSPITAL ASSOCIATION COMPANY.

Boston, June 28, 1915.

Mr. Editor: In regard to letter of Horace D. Arnold, M.D., in your issue of June 24th, the impression is conveyed that a gentleman of the Prudential Hospital Association Co., had made an unauthorized use of the Doctor's name.

We beg to state explicitly the Dr. Arnold, whose name our agent gave as reference, was Dr. Seth Arnold, a member of our hospital staff.

This physician too hastily reached the erroneous mental conclusion that there was only one Dr. Arnold (Horace D.), in Boston, whereas our agent knew only the one on his list, viz.: Dr. Seth Arnold.

This explanation shows no wrong intent on our part and through your kindness we trust that you will give space in your medical journal to correct the wrong impression this physician gave to Dr. Horace D. Arnold.

Yours very truly,
PRUDENTIAL HOSPITAL ASSOCIATION CO.
F. O. BLAZIER, President.

BELGIAN PHYSICIANS' RELIEF FUND.

REPORT OF THE TREASURER OF THE COMMITTEE OF AMERICAN PHYSICIANS FOR THE AID OF THE BELGIAN PROFESSION FOR THE WEEK ENDING JULY 17, 1915.

Pittsburg, Pa.

RECENT DEATHS.

DR. ROBERT HUGH MCKAY DAWBARN of New York, who died in that city on July 18, was born in Westchester County, N. Y., in 1849. He had been for many years professor of surgery at Fordham University Medical School and was connected with several New York hospitals. He received the degree of M.D. from the New York College of Physicians and Surgeons in 1881. He was appointed instructor in minor surgery at the College of Physicians and Surgeons in 1885, and in 1887 became professor of surgery and anatomy in the New York Polytechnic School. He was a frequent contributor to medical periodicals and in 1902 was awarded by the Philadelphia Academy of Medicine the Samuel E. Gross prize for the best original work in surgery during the previous six years. He was a member of many medical and scientific societies. He is survived by his widow, one daughter and two sons.

DR. FRANCIS DELAFIELD of New York City died of apoplexy on July 17 at Noroton, near Stamford, Conn. He was born in New York City on August 3, 1841, the son of a physician. He received the degree of A.B. from Yale University in 1860 and that of M.D. in 1863 from the New York College of Physicians and Surgeons. In 1863, after studying abroad, he became curator to the Bellevue Hospital, where in 1875 he was appointed visiting physician and in 1886 consulting physician. He was also pathologist at the Roosevelt Hospital and at the New York Eye and Ear Infirmary and was professor of pathology and of the practice of medicine at the New York College of Physicians and Surgeons. He was one of the founders and the first president of the Association of American Physicians in 1886. He has been distinguished as a medical writer as well as a practicing and consulting physician. The best known works of which he is author are "Handbook of Post-Mortem Examinations and Morbid Anatomy," "Manual of Physical Diagnosis," "Studies in Pathological Anatomy," "Diseases of the Kidneys," and "Handbook of Pathological Anatomy and History." He is survived by three daughters and one son.

DR. CHARLES PARKER HOOKER, who died of pneumonia on July 21, at Fortune Rocks near Biddeford, Me., was born in Springfield, Mass., on September 18, 1855, the son of a physician. After obtaining his early education in the local schools he undertook the study of medicine and received the degree of M.D. in 1879 from the Harvard Medical School. He early became associated with the Springfield Hospital and with the Mercy Hospital in Springfield, and maintained his connection with these institutions throughout his busy professional life. He was also for thirty years county physician of Hampden County. He was a charter member and former president of the Springfield Medical Club and a director of the Springfield Academy of Medicine. He was also a member of the American Medical Association and a Fellow of The Massachusetts Medical Society. He was a Councilor from the Hampden District from 1911 to 1914, having joined The Massachusetts Medical Society in 1879. He is survived by his widow, one daughter and one son.

THE TREATMENT OF ECZEMA WITH SPECIAL REFERENCE TO THE USE OF VACCINE AND THE PART PLAYED BY BACTERIA IN ITS ETIOLOGY. REPORT OF FIFTY CASES.

BY LEON S. MEDALIA, M.D., BOSTON.

INTRODUCTION.

This paper is based upon a study of about 50 cases of most protracted types of eczema. Practically all of these cases failed to respond to the ordinary methods of treatment, and applied for vaccine treatment as a last resort. The majority of these (46 cases) have been treated by me in private practice. Only a few (5 cases) have been followed up at my clinic at the Mt. Sinai Hospital. All but fourteen of these cases have been treated with autogenous vaccines.

While it is true that those cases treated in private practice have had the benefit of general treatment, such as dietetic, hygienic and the use of powders and ointments to alleviate the local condition alongside of the vaccine treatment, the cases at the out-patient clinic, on the other hand, received practically no other treatment but vaccines. The results obtained in this latter group of cases, in my opinion, are marked contributory evidence of the value of vaccines in this disease.

Only a few illustrative cases, the bacteriological findings, and the results obtained, will be cited in the body of this paper. The detailed

records of all the cases will be found at the end of the paper so that every one interested can draw his own conclusions.

ETIOLOGY.

I shall not enter upon a discussion of the various theories and opinions presented by different men from time to time upon the etiology of eczema. The principal thing I am interested in is the part played by bacteria in this disease as far as I could ascertain from my own work and from a careful study of the literature, both clinical and bacteriological.

The particular point in the etiology that I will try to make clear is that which Stelwagen¹ in his latest text-book on diseases of the skin considers the "unknown quantity" of eczema. He says, "It is a well known fact that certain external irritants will provoke a dermatitis in a large number of those exposed; whereas in most of these it will be simply a passing dermatitis; in others—usually a small minority—it turns out to be a true persistent eczema which has been provoked; what this necessary something is which is present in such individuals and not in others, and not constantly present in many of these, is the unknown quantity in eczema of which we are still ignorant."

What this "unknown quantity" is, ("this necessary something") suggested itself to me by the bacteriological findings of eczema and by the results obtained in this disease with the bacterial vaccines. Briefly, I believe this "unknown quantity" to be:—

1. The presence on the surface of the skin,

at the time that the dermatitis occurs, of an organism capable of causing a secondary infection;

2. The bacterial infection of the dermatitis by scratching, and

3. The lowered resistance of the individual and the lack of immune substances or antibodies in his blood to resist this secondary infection by the particular invading organism at the time when the dermatitis occurs.

The original dermatitis may be caused by chemical irritants in the individual's occupation as shown by Knowles,² or by poisoning with various food substances, or by mental and nervous disturbances, principally anxiety.

The particular organism which I believe causes the continuance of the dermatitis changing it into an eczema, that "unknown quantity" in the etiology, I found culturally to be usually a staphylococcus aureus, sometimes mixed with streptococcus and rarely mixed with staphylococcus albus. Although the raising of the resistance by vaccine had not in some cases prevented a recurrence of the dermatitis or primary lesions of eczema, it has prevented it from continuing as an eczema, the dermatitic lesions subsiding, as a rule, in a day or two without going on to the real eczematous condition.

Thus, while the primary cause of eczema may be any of the various etiologic factors capable of producing a dermatitis with or without the formation of vesicles, the real reason for the keeping up of this dermatitis, rendering it what we know as an eczema, is the secondary bacterial invasion. This claim is fairly substantiated, first, by the clinical findings, *i.e.*, the results obtained in this disease by vaccine and the behavior towards the vaccine treatment by those of my cases that have had recurrences, as will be cited later; and, second, by the bacteriological findings, *i.e.* the absence of bacteria in the primary lesions or closed vesicles and the abundant growth obtainable from the later more chronic lesions, crusts or pustules of the true eczema. (Similar bacteriological findings have been reported by Veillon,³ Kreibich,⁴ and a number of other investigators.)

BACTERIOLOGICAL FINDINGS.

Technic. Cultures were obtained in the usual way, using a number of swabs. The material was collected from unopened vesicles and crusts, from pustules and scales. It was then planted on glucose agar, beef blood serum and glucose bouillon. Occasionally, when thought necessary, special media were also used, principally blood agar. A number of cultures were made on glucose agar (usually fifteen to twenty) from which an autogenous vaccine was prepared in the ordinary way. As a rule, there was no difficulty in obtaining an abundant growth for the preparation of the autogenous vaccine within 24 hours,

if the cultures were obtained with the proper bacteriological precautions. Whenever a streptococcus was found mixed with the staphylococcus it was necessary to have it isolated in pure culture for the preparation of a separate autogenous vaccine. This, of course, took a longer time (two to four days) than when the staphylococcus alone was found present. When cultures were obtained from freshly formed vesicles, if the surface skin was properly cleansed with alcohol and allowed to dry before opening them and the proper aseptic precautions used in obtaining the material, the cultures were found invariably sterile.

Results. The cultural findings of the fifty-one cases of eczema to be reported were as follows: 34 cases showed staphylococcus *P. aureus* in pure culture; 2 cases showed staphylococcus *P. aureus* mixed with staphylococcus albus; 6 cases showed staphylococcus *P. aureus* mixed with streptococcus; 3 cases were found sterile; 6 cases no cultures taken.

Staphylococcus aureus, according to the above findings, may be said, therefore, to be the organism always present in eczema, while in only six of the forty-two cases (that showed growth) or little less than 2%, showed streptococcus mixed with the staphylococcus aureus.

The presence of streptococcus should always be kept in mind because it can very easily be overlooked on account of the abundant growth of the staphylococcus overgrowing it. The streptococcus, when present, if overgrown by the staphylococcus, can be detected only by the microscopic examination of smears made from the bouillon cultures or from the water of condensation of the solid culture media. It is of special importance not to overlook the streptococcus in connection with vaccine treatment where the results depend so much upon the proper autogenous vaccine.

VACCINE TREATMENT.

Method of Procedure. The cases treated in private practice were all given a thorough physical examination, preceded by a careful history. The urine, feces and blood were also examined. An attempt was made to find out if possible the underlying cause for the primary dermatitis or the beginning of the eczema. Special inquiry was made into the idiosyncrasies of the patient to various food articles in the diet; the effect of anxiety and worry upon the skin and the particular work done by the patient in his occupation or daily life—not being satisfied merely with a general statement of his occupation.

The examinations of the feces revealed the lack of proper mastication when present, the excess of carbohydrate, fat or meat intake, and the presence or absence of chronic constipation. Special attention was paid in the blood examination to the presence of low coagulability and of leukemia or other forms of anemia. The examination of the urine was made, with special ref-

* From a study of 4142 cases of eczema Knowles claims to have found a quarter of these to be due to external causes definitely. One-sixth of this affliction he claims is caused by the occupation of the individual.

erence to high urea or indicanuria and to rule out kidney lesions.

Inquiry into the habits and wearing apparel of the patient revealed as a rule the underlying mechanical reason for the eczema keeping up in certain places, such as the continuous irritation by clothing (woolen underwear), girdles and other wearing apparel; also the continuous picking at the face and scalp, or picking at the fingers and hands, all which habits had to be warned against and stopped before the patient could be really cured. Cultures were obtained as described under the previous heading, and an autogenous vaccine was prepared. Cases that applied for treatment during an acute exacerbation or those who had been suffering from an acute generalized eczema were advised to enter a private hospital, where they could be kept under close observation. The complete rest in the hospital, both mental and physical, and absence from the home surroundings, I consider an important factor in the good results obtained in such cases.

It was found early in the application of this method of treatment in eczema that autogenous vaccines were necessary and a still more important point was the need to administer what would be considered ordinarily tremendous doses up to 6000 million organisms or over, in one dose. Otherwise there would be no noticeable change in the condition clinically nor would there be much local reaction.

DOSAGE AND METHOD OF ADMINISTRATION.

From a recent article in the *Journal of the American Medical Association* (Greely, Feb. 6, 1915) it would seem that there is still a great need to emphasize the details of vaccine administration. I was astonished to see the attempt made in that article to lay down one set of rules with reference to dosage to be applied to all organisms and all kinds of infections. The fact remains that every kind of infection is a law unto itself, differing with each organism causing the infection as well as with each type of disease produced by the same organism. To say, for instance, that it is rare that "one (dose) smaller than 100 million organisms need be given as a first dose," without qualifying the kind of vaccine, is certainly erroneous. While it is true that in cases of staphylococcus vaccine the initial dose need not be smaller than 100 millions, in cases of pneumococcus, streptococcus, B. Coli, mucosus capsulatus and gonococcus the maximum initial dose should never exceed 25 millions.

Similarly, do we have to consider the different types of lesions. While, for instance, in a case of furunculosis, acne, or eczema the initial dose of staphylococcus vaccine may be 250 million organisms for all of them, in cases of furunculosis no higher subsequent dose than 1000 millions should be given, while in acne or eczema doses as high as 6000 or even 10,000 millions must be

given before any marked clinical change for the better is noticed.

As to the temperature being used as a guide to treatment, I can say that I have never found it useful. In the large number of cases I have had in various hospitals, where a morning and evening temperature chart was kept, I have thus far found in the temperature nothing that could be of use as a guide to the dosage or interval in the administration of vaccine. There would be an occasional drop in the morning temperature to 97°, but I could see no definite relation between these drops in temperature to the vaccine administration as indicating a negative phase. Such drops in temperature were noticed where the vaccines were omitted for several weeks, and again in cases where there was no vaccine treatment at all. Neither would the temperature be a practical guide, even if it were of any use in the treatment of ambulatory cases.

Personally I have used, and advised the various physicians by whom I was called in consultation to use, the local reaction as a guide both to dose as well as interval. Thus beginning with the minimum dose (25 million in all bacteria excepting staphylococci. In the latter the initial dose may be as high as 250 million in an average adult), it is gradually increased by 50% of the initial dose until the patient shows a local reaction. The inoculation should not be repeated until after the local soreness has subsided. If the local reaction was marked—marked local swelling and soreness of the upper arm, lasting more than 24 hours—the dose following should be decreased rather than increased. No general reaction should ever occur. When it does, it is a sign of an overdose. The intervals are guided by the local reaction in the arm in those vaccines that are prone to cause a local reaction, e.g. staphylococci, B. Coli, mucosus capsulatus. The interval may, therefore, be twenty-four to forty-eight hours in the first few injections and later once every five to seven days. Some organisms, e.g. gonococcus and pneumococcus, do not produce much of a local reaction, if any. The clinical response has to be depended upon alongside of the local reaction in such cases. The negative phase coincides with a change for the better. The reinoculation should take place when the change for the better begins slightly to wane. As a rule the dose may be repeated every twenty-four hours in acute cases and three to five days or seven days in subacute or chronic cases, always using the alternate arms (fleshy part of upper arm). In the acute cases, principally systemic, or in eye infections, only small doses must be used in order not to obtain much of a negative phase, because a set-back or a marked negative phase here might mean the loss of sight or life. It is particularly in those cases that experience and full knowledge of immunology is absolutely necessary, not only to obtain good results but also not to produce harmful effects. In the subacute and chronic diseases an overdose or a mistake in the interval is, as a rule,

from the very nature of the condition, not followed by any serious consequences.

The initial minimum dose may be definitely established. The maximum dose may also to some extent be set down according to the type of organism used and the kind of lesion treated—not to the same definiteness, however, as the minimum dose. The interval and frequency of reinoculation, upon which really depends the success or failure of this method of treatment—that can only be gained, I believe, by considerable experience. The best the general practitioner can do is to take a culture and have an autogenous vaccine prepared in a reliable laboratory, preferably by a man who makes a specialty of this mode of treatment rather than by one who knows the laboratory end of it only. The value of this procedure to the practitioner is threefold. First, he has a bacteriological diagnosis of the infection. Second, he can keep in touch with the man of experience during the progress of the treatment, consulting with him whenever necessary, thus giving the patient the benefit of the best procedure. And, third, he has a vaccine prepared from the organisms responsible for the infection. The expense of the autogenous vaccine, which can be prepared in the majority of cases within twenty-four hours, need not be any more, if as much, as the stock vaccine, and from the standpoint of results it certainly is the vaccine of choice.

The foregoing are really nothing more than general suggestions. Each case is a law unto itself, and considerable experience is necessary to accomplish the desired results with this method of treatment.

The details of the application of the vaccine in the disease under discussion—eczema—will be found in the illustrative cases following:—

ILLUSTRATIVE CASES.

The following cases are cited to illustrate the actual mode of application of vaccines in this disease—method of procedure, doses given, interval used, and results obtained.

CASE 33. M. S., female, 32 years, May 15, 1913. Had a dry scaly eczema for the last ten years. First started on right arm. Later the back of the neck became involved. Eczema has been there ever since. Has now an acute exacerbation for the last eight weeks with burning and itching all over the body. Examination showed skin of chest dry, inflamed and scaly. Eczematous patches also present on legs and feet and a fairly large patch on back of neck under hair line. Physical examination otherwise negative except for slight chronic alveolar trouble (pyorrhea). Bowels regular. Cultures from eczema scales and from surfaces underneath scales showed a pure growth of staphylococcus aureus, from which an autogenous vaccine was prepared. She received, on May 17, 200 million staphylococcus aureus vaccine; May 29, 500 million autogenous+500 aureus. Eczema improved on neck. June 3, 500 million autogenous+500 aureus; June 9, 1500 million autogenous+500 aureus. She received a similar

dose on June 14, 21, July 2, 16 and 26, the eczema improving steadily. She received another dose on Aug. 9 of 1000 million autogenous+500 million aureus and a similar dose on August 26, when the skin trouble all cleared up and remained well since. She has received eleven further similar treatments at an interval of from one to three months to keep up the immunity and prevent recurrence. She has gained in weight and is feeling very much better generally.

This case, a dry and scaly eczema of ten years' duration, the hardest type of eczema to respond to any method of treatment known, has readily yielded to the autogenous vaccine in large doses, remaining well for over one and one-half years. She has also shown a very marked improvement generally.*

The following case is probably the worst eczema case I had under observation. She responded in a most brilliant way to the vaccine. I cite it principally to show that the most hopeless case of eczema should not be given up without first trying the use of autogenous vaccine.

CASE 38. S. R., female, 58 years, Jan. 7, 1914. General diffuse running eczema of two years' duration. Started with swelling of the face. Lost all her hair. Continuous scaling, crusting, itching and burning, affecting her eyelids and mucous membrane of her mouth. Lost sense of taste shortly after skin trouble began. Stomach fair, bowels constipated. Examination showed skin of face, hands, neck, chest, arms, part of abdomen and thighs covered with profuse crusting and acutely inflamed and swollen in parts. Eye-lashes gone. Eyes lacrimating. Lids ectropic. Hair all gone. Considerable itching and crusting of scalp. Skin in parts infiltrated, cracked and desquamated. In parts denuded with some thin scales covering the denuded and bleeding surfaces. Urine negative. Feces showed marked carbohydrate fermentation. Cultures from eczema showed staphylococcus aureus from which an autogenous vaccine was prepared and administered. She received 36 treatments in doses ranging from 400 to 5500 millions, at an interval of one to two days at first and later from one to three-week intervals. Eczema was markedly improved Feb. 1 and was practically well on March 21, 1914. Has remained well since except for occasional dryness and chafing of exposed parts, like the back of the neck and arms during the winter months, but no itching or burning sensation has been present. Has had no true eczema since. Treatments were kept up once in two weeks to once a month or longer to prevent recurrence. Eczema has been well. Hair growing well and thick. Eyelashes grown. Taste regained two weeks after treatment was begun. Bowels regular and feeling well generally. Has gained eight pounds in weight and considers herself a well woman now.

This patient when first seen was advised to enter a private hospital, where she remained for four weeks. She was kept on a milk diet for a week, to which were added other articles of food very gradually.

* The stock aureus vaccine, made up of several strains, was used in small doses together with the autogenous in the hope of immunizing the patient in a prophylactic way against the possibility of later infections with other strains of staphylococcus aureus different from the one which the autogenous vaccine was made up of.

ually and cautiously. A daily morning washing with boric acid solution was given followed by a bland ointment.

The administration of her autogenous vaccine in large doses, together with the complete rest and change from her home surroundings, which were not very conducive to her getting better, as well as the topical applications, all helped, no doubt, to the rapid successful outcome of this case.

The idiosyncrasy to certain articles of food as a cause of skin affection is well known to everyone, a good example of which is fish poisoning. The relation of such food poisonings to eczema is referred to by standard text-books on skin diseases. The following case is a good illustration of poisoning by eggs.

CASE 42. L. A. C., female, 42 years, applied for treatment April 8, 1914. Complained of a vesicopustular eczema of face of twelve years' duration. Skin of face covered with a vesico-pustular eruption and generally much inflamed. When she was sixteen years of age she suffered considerably when eating anything with eggs in it. Urine negative, except for low specific gravity (1008). Feces examination was found negative. Cultures from the vesicles and pustules showed staphylococcus aureus and a few chains of streptococcus. Autogenous vaccines were made up and administered at 3- to 12-day intervals. She received nine treatments in all. She left on her vacation May 22, face practically well. Owing to her idiosyncrasy to eggs she was advised to take eggs sparingly, increasing it gradually. The leaving out of eggs in her diet helped, I believe, in the successful results obtained in this case.

Very striking illustrations of food sensitization as a cause of asthma and eczema, and the treatment of the same by immunization with increasing doses of white of eggs, have been reported by Talbot.⁵ Although Talbot was able to help the milder types of asthma and eczema by gradually increasing doses of the particular protein that caused the poisoning, he was unable to help the more severe types in the same way. I believe his failure to be due in part, at least, to his neglect to take into account the bacterial invasion. Though it is secondary to the food poisoning, the condition will not be ameliorated, I believe, by the removal of the primary cause alone, after the secondary bacterial infection is once established.

The following two cases are good illustrations of the part played by mental anxiety and worry in eczema.

CASE 47. C. W. W., male, 52 years, first applied for treatment May 8, 1914.

He had an acute eczema which began four months previous "following a cold." Had considerable business worry at that time. The eczema first began with swelling and serous oozing inside the ear, spread on the outside and to other parts of the body. Examination showed eruption of face, neck, ears and outer side of right thigh. Face, ears and neck markedly swollen, with considerable oozing, crust formation, vesicles and pustules. He was at once

sent to a private hospital where he could be properly attended to. Cultures showed a pure growth of staphylococcus aureus, from which an autogenous vaccine was prepared and administered, at first every day and later every 3 to 12 days, in doses ranging from 250 to 6500 millions. Improvement was noticed 24 hours after first inoculation. He left the hospital on the sixth day, markedly improved. Improvement kept up steadily. Skin was practically well until Oct. 19, when he was under considerable nervous strain and business anxiety, at which time he had recurrence of swelling over his eyes and oozing behind the ears, which subsided in a few days. He had one treatment on Oct. 19, since which time he has been well. He received 19 treatments in all. The dose that was necessary to produce any effect upon this patient, as in a great many others with eczema and acne, was tremendous, reaching up to 6500 million organisms.

The other case where anxiety showed a definite relation to a recurrence of the eczematous eruption was that of:

CASE 46. K. E. J., male, 46 years. First consulted me on Apr. 31, 1914, for eczematous eruption of face, neck and hands, of sixteen years' duration. The eczema first began in 1898 while in Cuba, with vesicles and serous oozing of fingers, which spread to the dorsal surfaces of hands and wrists. In 1911 he was treated by his physician with stock staphylococcus aureus vaccine obtained from me. The eczema cleared up and he remained free from it until last summer when it recurred. He was again treated with the same stock staphylococcus, with no effect this time. The eczema was getting worse, spreading to face and neck, when he was sent in to me for treatment with autogenous vaccine. Examination showed skin of dorsal surfaces of hands covered with a vesico-pustular eruption, marked oozing upon the slightest disturbance of the surface scales or crusts and cracking of fingers. Similar eruption present on skin of upper arms, neck and face. Urine negative except for high urea (3.2%). Feces showed a carbohydrate fermentation. Cultures from the various lesions showed an abundant growth of staphylococcus aureus from which an autogenous vaccine was prepared and administered. He received twenty-six treatments in all at three to ten-day intervals in doses ranging from 500 to 4000 million of organisms. Eczema improved markedly after the third treatment. The face and neck and forearms were free from trouble seven weeks after beginning of treatment (June 22). On August 21, skin practically well. Was told to come back in two weeks. He turned up Sept. 14th with a marked recurrence of the eczema on hands and fingers, stating that his only child was very ill and the doctor told him that he might lose her. He was very much worried over it and the skin began to break out about that time. He was well until that time. He was given three more treatments. The eczema again cleared up. He has been well since.

I believe that the recurrence in these two cases can be attributed in great part to the mental anxiety and that it was a little more than a coincidence.

The following case is a good example of an occupational eczema:

CASE 36. Male, 54 years, optician was first seen on Oct. 20th, 1913. Face and scalp covered with a vesico-pustular eruption with considerable itching, of two months' duration. A careful investigation of his occupation revealed the fact that he does considerable developing of photographs. The careless scratching of his face and scalp while at work, transferring some of the developing fluid to the more delicate skin of these parts started a dermatitis, probably due to the metal poisoning in the developing fluid. This dermatitis became infected with the staphylococcus and produced a true eczema. The hands showed the affection only to a slight extent. Urine negative. Feces examination showed a carbohydrate fermentation. Cultures from the vesicles and pustules showed a pure staphylococcus aureus, from which an autogenous vaccine was made up and administered. He received eight treatments in all at an interval of from three to twelve days in doses ranging from 250 to 2000 million, and was discharged cured (Dec. 6, 1913), six weeks after treatment was begun. He has had no recurrence since. This patient has been again doing developing for over a year now, being careful not to touch his face at the time, without a return of his trouble. Beside the vaccine the patient received a calamine wash to allay the itching. He was ordered not to touch the developing fluid for a while and to *let his face alone*.

This case illustrates the importance of inquiring into the man's occupation as to what he actually does and not being satisfied with a general statement. His being an optician would never have revealed the fact that he actually was doing developing, which was the underlying cause of his complaint. I do not believe that this patient could have resumed his work in developing, without a recurrence, for over one and one-half years, unless the use of autogenous vaccine had rendered him immune to the secondary staphylococcus infection. Recurrences of the dermatitis due to the metal poisoning might have taken place, but they probably were so slight without the subsequent infection that they remained unnoticeable.

RESULTS.

The results obtained in these fifty-one cases can be briefly summarized as follows: Cured, 43 cases. Of these there were eight cases that had one or more recurrences, which yielded readily to from two to four treatments of their autogenous vaccine.

Improved, 6 cases.

No improvement, one case.

Results unknown, one case.

The number and duration of treatments were as follows:

Minimum number of treatments, 3.

Maximum number of treatments, 41.

Average number of treatments, 12.

Minimum duration of treatment, 2 weeks.

Maximum duration of treatment, 12½ months.

Average duration of treatment, 11 weeks.

Forty-five of the 51 cases here reported have been of the vesico-pustular and weeping variety.

The remaining six were of the dry and scaly type. Two of the six were improved. Four were cured. The difficulty with some of the scaly types is that no cultures are obtainable and hence no autogenous vaccine can be prepared and they have to be treated with stock vaccines.

I wish to refer here to the results obtained with this method of treatment by various other men, as found in the literature.

Gilchrist⁶ of the Johns Hopkins University reported 60 cases of eczema, 20 of which were markedly benefited, 20 were moderately benefited, and the effect on the remainder was nil. He used principally stock staphylococcus albus vaccine. He claims to have obtained most marked results in seborrheic eczema. After that the pustular and weeping eczemas were most benefited, while the scaly and indurated patches were not at all affected.

The surprising thing to me is that Gilchrist obtained as many good results as he did with stock vaccine and staphylococcus albus at that, because almost all the cases of eczema in my series and those of other men who have made a bacteriologic study of eczema (as already referred to—see under "bacteriology") showed the predominating growth to be staphylococcus aureus.

Smith⁷ reports over 40 cases of eczema treated with the staphylococcus albus vaccine. The type which responded best he claims was the so-called eczema squamosum. In many of these cases the results were excellent. Pruritus, which was marked in a large per cent. of the cases, disappeared rapidly. He came to the conclusion from the clinical reaction of these cases to the vaccine that the staphylococcus is not necessarily pyogenic and that it is capable of setting up a dermatitis corresponding to certain types of the so-called eczema.

Other authors reported varying numbers of cases treated by vaccines with invariably good results. (Hazen,⁸ Davis,⁹ Farrell¹⁰ and McDonald.¹¹)

Perhaps the most striking example showing the fallacy of treating all eczema cases with stock staphylococcus albus vaccine as recommended by Gilchrist is the following case:—

CASE 25. C. C., male, 27 years, Jan. 19, 1912. Very marked vesico-pustular eczema over face, forearms, chest and legs, with considerable inflammation. Has had it on and off for the last seven years. Suffers now considerably with itching and burning night and day. Feces showed small, hard, marble-like pieces (sheep manure). Abundant undigested muscle fibers. Urine negative. Cultures from pustules and oozing surfaces of eczema showed staphylococcus aureus and long chains of streptococci, the latter predominating. He had eleven treatments of autogenous staphylo- and streptococcus vaccines at an interval of from five to seven days. Duration of treatment two months. There was a very marked improvement after third inoculation. Eczema practically cleared up. Was entirely well March 16. Discharged cured. Has had no recurrence of the eczema since.

Without the individual bacteriologic investigation and the use of the autogenous streptococcus vaccine, I believe that this case, as well as the other five cases, where streptococcus was found culturally, would have had to be reported as failures.

SUMMARY AND CONCLUSIONS.

1. Eczema in its primary stages is in reality a dermatitis, the exciting cause of which may be any external or internal irritant capable of exciting a dermatitis.

2. The "necessary something" or the "unknown quantity" in the etiology referred to in the text books, responsible for changing the dermatitis into a true eczema is the secondary bacterial invasion of the dermatitis.

3. The absence of bacteria in the primary or dermatitis stage of eczema and the abundant growth obtainable from the secondary or true eczema lesions, together with the clinical response to the autogenous vaccines—all fairly well substantiate the etiologic relation of bacteria to this disease.

4. *Staphylococcus aureus*, according to my findings, is the organism always present in eczema, at times mixed with streptococcus and rarely mixed with *staphylococcus albus*.

5. The general condition, food idiosyncrasies, habits and occupation of each individual patient should be carefully studied in order to eliminate if possible the exciting causes of the dermatitic lesions.

6. Ointments, powders and other topical applications, though temporary in their effect, are necessary adjuncts to the vaccine treatment to protect the raw skin and help to relieve the patient's discomfort.

7. The presence of the streptococcus should always be kept in mind and when found a separate autogenous vaccine should be prepared therefrom.

8. The use of large doses—6000 million organisms or over—of the autogenous staphylococcus vaccine was found necessary for the successful treatment of this disease.

9. Vaccine treatment, more especially the use of autogenous vaccine, when administered in the proper doses, yields by far the best results in the treatment of this intractable disease—eczema.

In concluding I wish to thank Dr. Charles J. White for his helpful suggestions in the preparation of this paper.

CASE REPORTS.

CASE 1. M. W., female, June 20, 1908. Complained of eczema of the hands off and on for several years. Indurated eczematous patch about the size of a half dollar on the right wrist for the last four months. *Staphylococcus opsonic* index on beginning treatment was .65. She received 3 treatments of staphylococcus stock vaccine at intervals of 3 and 6 days, when she left on her vacation. Returned in September somewhat improved. Received 10 more treatments, at the end of which time the eczema was practically well. Was given 5 further treatments and was discharged cured, Jan. 2, 1909. *Staphylococcus opsonic* index on date of last treatment was 1.04.

CASE 2. M. H. F., male, 55 years, Dec. 7, 1908. Complains of eczema on hands of 25 years' duration. Vesicles and pustules. Considerable itching and oozing. Cultures from unopened vesicles were found sterile. Cultures from pustules and oozing surfaces showed *staphylococcus aureus*. He also had a chronic alveolar osteomyelitis (pyorrhea) which showed a mixed infection of pneumo-, staphylo- and streptococci. *Opsonic* index was staphylo., .58; pneumo., .61; strepto., .84. He received six treatments. Was discharged cured. The *opsonic* index was up on Jan. 19 to staphylo. 1.19 and pneumo. 1.30.

CASE 3. L. W. I., male, 26 years, July, 1909. This patient when he applied for treatment had a very marked form of generalized weeping eczema covering arms, shoulders, chest, part of face, ears and small areas throughout the rest of the body. Marked erythematous and squamous patches with vesicles and pustules. Very considerable serous oozing, marked swelling of ears and crust formation behind ears. Has been suffering considerably from itching and pain. The condition first started about a year ago. Has been growing worse steadily. Had no relief from any local applications. He received 41 treatments at 2- to 5-day intervals and was discharged cured Oct. 28 (a little over three months). He remained well until Dec. 11, 1912, when he came back with a mild recurrence, showing small areas on dorsal surfaces of hands covered with a vesicular eruption. Few vesicular patches also present on face. Skin otherwise negative. Urine negative except for high urea (3.4%). Cultures showed pure *staphylococcus aureus*. He received two treatments with autogenous vaccine. Was discharged cured again Dec. 14, 1912. Has been well since.

CASE 4. H. A. L., male, 41 years, July 24, 1909. Had eczema on hands for 16 years. Complains now of eczema of legs of 3 years' duration. Eczema patches are dry, red and scaly. No oozing. Bowels

regular. General condition good. Cultures from eczema negative. Cultures from nose showed staphylococcus aureus. Was given 5 treatments of stock staphylococcus aureus at 3- to 7-day intervals. Came back 6 weeks later and received one more treatment. Was discharged cured. Has been well since.

CASE 5. R. S., female, 40 years, Sept. 1, 1909. Has an eczematous eruption of hands of 12 years' duration. Is worse during the winter. No other parts of body affected. Bowels constipated. Received 3 treatments at weekly intervals and was discharged well Oct. 20, 1909. Came back Nov. 26, 1910, with some desquamation of hands. Was given 2 treatments. Discharged cured. (Could not be located by letter).

CASE 6. F. T., male, 6 years, Dec. 19, 1909. Complained of eczema of one year's duration. Subject to colds which hang on for a long time. Eczema cultures were found sterile. Was given 11 treatments of staphylococcus and pneumococcus vaccine at 5- to 14-day intervals. At the end of the 3d inoculation the itching had all gone. Pimples still present. After the eighth inoculation the eczema was all cleared up. No itching. Had 3 more treatments and was discharged cured, June 18, 1910. "Has been well since."

CASE 7. H. A. H., male, 69 years, Feb. 22, 1910. Complains of eczema in popliteal space. Believes it began following a carbuncle two and a half years ago. Has been having boils of neck and scalp ever since. A number of small furuncles present on scalp now. Very painful and indurated. Urine showed a great many colon bacilli, free and clumped pus. Cultures from boils and eczema showed a pure staphylococcus aureus, from which an autogenous vaccine was made. He received six treatments at 3- to 14-day intervals. Discharged cured. Came back three months later (July, 1910) with a slight recurrence of furunculosis. Was given three more treatments. Discharged cured.

CASE 8. C. R. R., male, 35 years, Feb. 26, 1910. Complained of acute eczema of face. Father had eczema and mother had psoriasis. Eczema started with red patch over chin. Is growing worse. Skin of whole face shows yellowish crusts and scales, with some oozing. No lesions on any other part of body. Staphylococcus opsonic index was .67, strepto., .87; pneumo., .58 and colon, .77. Cultures showed staphylococcus aureus. Urine cultures showed staphylococcus albus. Autogenous vaccine was made up and administered. He was given five treatments at 2- to 10-day intervals. Showed little benefit. Discontinued treatment against advice.

CASE 9. H. S. W., female, 34 years, Apr. 28, 1910. Had eczema when a baby. Remembers having had it for years. Then it disappeared, remaining on flexor surfaces of elbows only. Two years ago it recurred with a rash on face. Lasted for over a year. Got better. Complains now of same kind of outbreak. Examination showed a typical acute eczema in the vesicular stage, with red patches and pin point vesicles. Opsonic index was staphylococcus, .66; streptococcus, 1.07; pneumococcus, .89 and colon, .87. She received seven treatments at 4- to 7-day intervals and was discharged well on June 13, 1910. She returned about two years later (Apr. 18,

1912) with a very slight recurrence. Was given six more treatments and was discharged well June 6, 1912. Has had no recurrence since.

CASE 10. K. F. B., male, 57 years, June 18, 1910. Eczema of face on and off for the last two years. Bowels very much constipated. Urine negative. Eczema cultures showed pure growth of staphylococcus aureus, from which an autogenous vaccine was prepared. He received 8 treatments at intervals of from 4 to 14 days. Was discharged cured Aug. 8, 1910. Has had no recurrence.

CASE 11. L. A., female, 24 years, June 20, 1910. Father troubled with a generalized eczema. Patient complained of scaly eczema on various parts of body. Began on legs and gradually spread upwards. Has been breaking out on her face for the last three months. Cultures from eruption were sterile. Stock aureus vaccine was administered. She received six injections in all at intervals of from 3 to 7 days. Face showed marked improvement after second treatment. Eczema on the whole better when she discontinued treatment three weeks later July 14, 1910.

CASE 12. A. C. W., female, 39 years, Aug. 1, 1910. Has vesicular eczema of hands and fingers of four years' duration. Eczema began with swelling of both hands. Swelling disappeared soon after, leaving the vesicles, which got better in the winter. Every summer after that vesicles would reappear, getting worse each time until it finally formed into the continuous and confluent eczematous condition present now. Boils and carbuncles off and on for last four years. Bowels constipated. Feces fomented, darkish green, very foul. Urine negative. Cultures from oozing surfaces showed pure growth of staphylococcus aureus. She had 12 treatments at an interval of 3 to 5 days, and was discharged cured Oct. 11, 1910. The constipation was overcome to a great extent by agar agar and increase in the amount of water taken.

CASE 13. R. H. A., female, 28 years, Oct. 14, 1910. Applied for treatment of chronic eczema, which she had ever since she was six months old. "Chiefly dry, rough and scaly. Not moist type." Has now a vesico-pustular eczematous eruption of face and neck. Practically no oozing. Had a bad attack of urticaria ten years ago, which kept recurring, at times as often as twice a week, until last May. Has to be very careful with her diet. Cannot eat fish, strawberries, tomatoes or veal without getting poisoned by it. Bowels very constipated. Takes pills and laxatives continuously. Was in a private sanatorium for seven months without relief. Urine normal. Feces showed very marked carbohydrate fermentation. She received 14 treatments of stock vaccine at intervals of from 3 to 10 days. Discharged cured as to eczema. When last seen, December, 1912, eczema was still well. Was heard from on Feb. 9, 1915, in answer to a letter of inquiry, that except for occasional slight passing eruption in the winter she has been very well.

CASE 14. S. F. P., male, 36 years, Jan. 14, 1911. Complains of eczema of hands of 18 years' duration. First appeared with yellow blisters associated with intense itching. Skin generally sensitive. Urine negative except for urea (3.1%). Cultures from pustules showed pure staphylococcus aureus.

Staphylococcus opsonic index was .49. Autogenous vaccine was prepared and administered. He received 22 treatments at 4- to 10-day intervals. On April 24, 1911, was markedly improved. Discontinued treatment against advice. When last seen, January, 1915, he said that eczema was well since he was treated and is well now.

CASE 15. H. F. R., male, 60 years, Feb. 6, 1911. Complained of a dry, scaly eczematous eruption on ankles and on both legs, of several years' duration. Had been treated for it for two years with ordinary treatments with no relief. He received four treatments with stock vaccine at 5- to 10-day intervals when eczema was all well. Was given 4 further treatments at intervals of from 3 to 4 weeks as a prophylactic measure and was discharged cured.

CASE 16. L. I., male, 3 years, Feb. 13, 1911. Eczema of hands and face of two years' duration. Scroptular eruption present now over face, ears, both hands and wrists. Constipated since he was born. Takes cathartics and enemas all the time. Cultures from the pustules showed a pure staphylococcus aureus from which an autogenous vaccine was prepared. He received 15 treatments at 3- to 10-day intervals. After the second treatment eczema was markedly improved. Improvement continued steadily until March 31, when there was no more itching or oozing. On May 12, the eczema had all cleared up. He received 2 more treatments and was discharged cured May 25, 1911. Has had no recurrence.

CASE 17. L. Z., male, 52 years, May 1, 1911. Complains of eczema of five years' duration. First started on right leg. Spread quickly over legs, thighs, hands and face. Began with little blisters. Itching very intense day and night. Bowels constipated. Urine negative. Staphylococcus opsonic index was .62; colon .62. Cultures showed a pure growth of staphylococcus aureus from which an autogenous vaccine was prepared. He received 13 treatments at intervals of 5 to 11 days. Eczema was markedly improved after the third inoculation. Improvement kept up steadily until Nov. 23, 1911 when he was sent off for a month. He received six more treatments at one to two month-intervals and was discharged well, May 14, 1912. He returned Sept. 17, 1912 with a slight recurrence which was relieved by three further treatments (Sept. 17, 24 and Oct. 1). He returned again on March 25, 1913 with a slight itching on thigh. Was given one treatment on that date and another on March 31. Was well until Oct. 24, when he returned with a slight swelling around eyes and around chin. Had one treatment on the same date and another on Oct. 30, 1913. Has been well since.

CASE 18. T. F. L., male, 48 years, May 31, 1911. Complains of itching of head, particularly behind the ears, with some oozing. Examination showed psoriatic patches round elbow joints, smaller spots on hands and other parts of the body. Few patches on scalp. Behind ears there is an erythematous and scaly eruption, very itchy, with serous oozing. Urine negative. Feces fomented, not formed and foul, with large amounts of unchewed and undigested meat remains, vegetable and starch remains. Cultures showed predominating staphylococcus aureus and few chains of streptococcus. He received eleven treatments in all at an interval of from 5 to 7 days. Eczema was cured, psoriasis showed slight improve-

ment. The opsonic index when he first began treatment was staphylo., .61; strepto., 1.11; pneumo., 1.05; and colon .49. No other opsonic tests were made.

CASE 19. C. R., female, 19 years, Aug. 16, 1911. Complains of vesicular and squamous eczema over arms, face and neck and back of ears of fifteen years' duration. Bowels slightly constipated. Physical examination negative except for slight presystolic murmur. Feces was found to be made up of small hard marble-like pieces (sheep manure). Urine negative. Cultures from oozing surfaces showed pure growth of staphylococcus aureus. She had twelve treatments in 3½ months at an interval of from 3 to 7 days. She showed very marked improvement. Left on her vacation. Has not been heard from since.

CASE 20. H. H. C., male, 51 years, Sept. 19, 1911. Complained of eczema of feet and ankles of 12 years' duration. First came on while in the Philippines. Began with acute ulcerative condition of soles of feet which disappeared at the end of about three weeks. This was followed by an eczematous condition which has kept up since. Physical examination negative. Cultures showed staphylococcus weak aureus. An autogenous vaccine was made up and sent to his physician in Washington who kept up treatment. When seen again on his visit to Boston, Dec. 8, 1911, eczema was well. He had no trouble since.

CASE 21. M. S. W., male, 60 years, Sept. 21, 1911. This patient was referred for treatment for an infection of the left antrum. He also had an old standing erythematous vesico-pustular eruption on face and other parts of body. Urine negative. Feces unformed, fomented and foul. Marked increase of starch and muscle fibers. An autogenous vaccine was made up from the pus obtained from the antrum, organisms staphylococcus aureus and streptococcus. He had four treatments with autogenous vaccine mixed with stock aureus (cultures were not obtained from the eczema) at intervals of from 5 to 8 days. Treatments were continued by his family physician in Washington, and while on his vacation for about 12 months. There was marked relief in the discharge from the antrum while the vesicles and pustular eruption was entirely cured when last seen (Nov. 2, 1911). Had no recurrence of eczema since.

CASE 22. R. M., male, 31 years, Sept. 30, 1911. Eczematous eruption and cracking of skin of right hand of one year's duration. Gets worse in cold weather. Very marked itching. Had eight treatments at 7 day intervals. Was discharged cured. Has not been seen since. Could not be located by letter.

CASE 23. L. B. A., female, 6 months, Oct. 31, 1911. Had eczema all over body since she was one month old. Father's brother has eczema. Bowels somewhat diarrheal. Had been always breast fed. Eczema growing worse all the time. Cultures showed a pure growth of staphylococcus. An autogenous vaccine was made up and administered. She received 4 treatments at intervals of 5 to 9 days. Received one further treatment one month later and was discharged well. Five months later (May 2, 1912) she returned with a slight recurrence. Was given one treatment and has been well since.

CASE 24. G. I., female, 16 years, Dec. 26, 1911. Had eczema when a child. Has practically never been free from it. Used an ointment to relieve the itching. Has now eczema behind ears with marked oozing and fissuring, spreading upwards towards scalp. Skin otherwise negative. Urine negative. Feeces not formed, very foul, fomented, considerable undigested vegetable and meat remains. Cultures showed pure staphylococcus aureus. She had 6 treatments at an interval of 1 to 2 weeks. The eczema disappeared and remained well up to Oct. 19, 1913 (one year and eight months), when she showed a very slight recurrence. She received seven more treatments and was discharged cured Jan. 3, 1914. Has been well since.

CASE 25. Included in the body of the paper.

CASE 26. M. W. E., female, 45 years, Jan. 27, 1912. Had eczema of face all her life. Had never been free from it. Skin of face covered with erythematous and pustular eruption. Skin over other parts of body in good condition. Had electric treatments with no relief. Urine negative except for high urea (3%). Cultures from pustules showed staphylococcus aureus and chains of streptococci. An autogenous vaccine was made up. She received 12 injections at intervals of four to 21 days. Was discharged well May 14, 1912.

She returned 11 months later (April, 1913) with a recurrence of the eczema. She was given eight more treatments at three- to nine-day intervals and was discharged cured, June 23, 1913. Has been well since.

CASE 27. P. E. L., male, 63 years, May 4, 1912. Physician. Has had eczema of right leg for last six years. Has some eczematous eruption on face. No relief obtained from local applications or x-ray treatment. Cultures from eczema showed staphylococcus aureus and albus from which an autogenous vaccine was prepared. He received 17 treatments at two- to eight-day intervals. Eczema showed marked improvement after the first few injections and continued improving steadily. Eczema was well August 19, 1912. Has had no recurrence.

CASE 28. D. E. M., female, 35 years, June 1, 1912. Had erysipelas three years ago. Skin of face and around mouth troubled her for a couple of months after. Skin became better but not quite well. Skin of face became very much worse the last two months. Marked itching and burning. Spread all over face within the last three weeks. Feels drawn, dry and hot. A typical erythematous and in parts squamous eczema. Has also a marked advanced stage of chronic alveolar osteomyelitis (pyorrhea). Several teeth loose. Considerable pus around many of them. Gums spongy and receded. Cultures from eczema showed staphylococcus weak aureus and albus. Urine negative. She had six treatments at intervals of five to seven days. Duration of treatment five weeks. Eczema was all well following the third treatment. She continued treatment for her gums. Discharged cured as to eczema July 6, 1912.

CASE 29. S. M., female, 6 months, Aug. 30, 1912. Eczematous rash present all over body. First came on during the hot weather a month previous. Started on her legs and back. Gradually covered whole body. Breast fed. Is not constipated. Has

a great deal of itching. Keeps her awake nights. Cultures from pustules showed staphylococcus weak aureus. She received four treatments in all, the first two at intervals of five days, the last two at two- and four-week intervals. After the second injection the eczema was practically cured. Received the last two injections prophylactically. Discharged cured Oct. 15, 1912.

CASE 30. H. I. W., male, 92 years, Sept. 23, 1912. Has erythematous eczema for last two years on upper arms, legs, wrists, face and neck. Is worse on the face. Bowels constipated (small, hard marble-like pieces). Urine showed heavy trace of indican. Otherwise negative. Cultures showed a pure growth of staphylococcus aureus. An autogenous vaccine was made and administered. He received six treatments at intervals of six to 14 days. Eczema improved considerably; itching less and skin looked better. Discontinued against advice. Was getting on fairly well when last heard from.

CASE 31. B. L. T., male, 37 years, Oct. 8, 1912. Eczematous eruption on left foot of seven years' duration. Itching worse at night. Eye lids also involved. Has been getting worse gradually. Resisted various treatments by eye specialist who sent him in for vaccine treatment. Cultures showed a predominating growth of staphylococcus weak aureus and an occasional chain of streptococcus. An autogenous vaccine was made up. He received 11 treatments at five- to 21-day intervals, when his eczema had entirely cleared up. Received one more treatment seven weeks later and was discharged cured. Has had no recurrence.

CASE 32. F. P. J., male, 55 years, Jan. 23, 1913. Squamous eczema of hands, forehead and back of ears; elbows and legs especially bad, soles of feet scaling markedly. Thirty years' duration. No vesicles present at present time. Typical case of eczema squamosum. Physical examination otherwise negative. Urine negative. Stool watery. Very foul. Considerable undigested meat and starch remains. Cultures from oozing surfaces obtained by removing the scales showed staphylococcus weak aureus. He had four treatments at two- to four-day intervals. There was a slight improvement. Left on his vacation and has not been heard from since.

CASE 33. Included in body of paper.

CASE 34. K. L., female, 21 years, Oct. 6, 1913. Complains of eczematous eruption on right middle finger of four years' duration. Skin of finger dry and cracked with considerable itching. Aene of face for several years. Skin otherwise negative. Cultures from eczema showed a pure growth of staphylococcus aureus from which an autogenous vaccine was prepared. She was given eight treatments at four- to 21-day intervals when she was discharged cured. Eczema showed marked improvement after third injection and continued well until discharged cured, Oct. 13, 1913. No recurrence since.

CASE 35. S. N., female, 36 years, Oct. 8, 1913. Eczematous eruption of many years' duration. Examination showed marked eruption with small blister-like papules on skin of flexor parts of elbows, extending upwards to shoulders, front of neck, back of neck and on inner side of right thigh. Skin

cracked and excoriated with intense itching. Urine negative. Cultures showed a pure growth of staphylococcus aureus. An autogenous vaccine was prepared. She received 19 treatments at intervals of three to seven days. Had four further treatments at three- to eight-week intervals. Eczema showed improvement at the end of the second treatment and was practically well after the fifteenth (Nov. 28). Was discharged cured May 1, 1914. Has had no recurrence since.

CASE 36. Included in body of paper.

CASE 37. B. A., male, 6 months, Dec. 29, 1913. Eczema of greater part of body. First started when two months old, on side of face and head. Cultures from oozing surfaces and crusts showed pure staphylococcus aureus from which an autogenous vaccine was made and administered. He received seven treatments in all, at intervals of from three to nine days. Eczema showed improvement after third inoculation and was practically well after the fifth inoculation, Jan. 26, 1914. Has not been heard from since.

CASE 38. Included in body of paper.

CASE 39. K. H. R., female, 38 years, March 3, 1914. Complaints of burning and itching eruption on face of one year's duration. Eruption would start with small blotches and papules coming to a head. Not much pus present. Urine negative except for urea (2.2%). Cultures showed pure staphylococcus weak aureus. An autogenous vaccine was made up and administered. She received seven treatments at five- to seven-day intervals when she was discharged cured, April 23, 1914. Has had no recurrence.

CASE 40. B. J. M., male, 4½ years, March 31, 1914. Had eczema ever since he was five months old. Very bad the last four weeks. Asthma for the last year and a half. Examination showed hands, elbows and neck covered with a weeping eczema with crusts and open wounds. Lungs show typical asthmatic condition. Urine negative. Cultures showed pure staphylococcus aureus, from which an autogenous vaccine was made. He received 11 treatments in all, at intervals of from four to 14 days. Eczema showed marked improvement at the end of the third treatment. Improvement continued steadily. Discontinued treatment against advice June 6, 1914. Eczema much improved.

CASE 41. L. C. I., female, 36 years, April 2, 1914. Eczematous eruption on right middle finger and on dorsal surface of left hand. Finger began to trouble her 14 years ago and trouble continues to recur at intervals. One brother has eczema. Cultures made from the serous oozing showed a pure staphylococcus aureus from which an autogenous vaccine was prepared. She was given six injections at intervals of four to 21 days. The eczema showed marked improvement after the second treatment. Improvement continued until the sixth injection, May 7, 1914, when the skin was entirely healed and well. Was given three more treatments and was discharged cured, July 1, 1914. Has been well since.

CASE 42. Included in body of paper.

CASE 43. R. C., female, 44 years, April 18, 1914. Had eczematous eruption for last three years, principally on hands. The last week she had a very acute pustular eruption all over palms of hands, worse on right hand. Cultures showed pure growth of staphylococcus aureus. She received bi-weekly treatments for the last ten weeks. Very marked improvement at the end of the eighth treatment. Kept on improving steadily. Skin has been all well since Aug. 15, 1914.

CASE 44. P. M., female, 32 years, April 21, 1914. Had sero-purulent eczema on face and dorsal surfaces of hands for five months. Skin showed many serous pustules. Bowels very constipated. Feces showed marked carbohydrate fermentation. Cultures from the pustules showed a pure staphylococcus aureus. An autogenous vaccine was made up. Was given 14 treatments at intervals of from two to seven days when she was discharged well. Has had two more prophylactic injections at intervals of three weeks. Has been well since. This case was very troublesome on account of a general erythema, soreness and marked inflammation of the face which persisted until it finally yielded to the vaccine.

CASE 45. T. M., male, 54 years, April 22, 1914. Complaints of squamous and pustular eczema for last four years, mostly on neck. Erythematous patches and itching also present on back and the inner surfaces of thighs. Cultures showed staphylococcus aureus. Was given five bi-weekly treatments. Showed much improvement and left off treatment on account of leaving town (June 3). Returned to town again, resuming treatments Sept. 23. Received nine treatments. Is practically well. Still under observation. Treatments were bi-weekly.

CASE 46. Included in body of paper.

CASE 47. Included in body of paper.

CASE 48. G. D. A., male, 17 years, July 13, 1914. Complaints of eczema since he was six weeks old and of asthma of eleven years' duration. Skin of neck and under both knees in popliteal space showed scales and small vesicles and pustules. Lungs showed a typical asthmatic condition. Urine acid in reaction, very slight trace of albumen and high urea (3.5%). Feces showed marked carbohydrate fermentation. Cultures from the eczema showed pure staphylococcus aureus from which an autogenous vaccine was made and administered. Patient was sent to a private hospital and was given 11 injections at intervals of one day, when he was sufficiently well to leave hospital. Was given nine further treatments at intervals of from two to seven days. Showed marked improvement in both eczema as well as asthma. Left for school Sept. 15, markedly improved.

CASE 49. L. S., male, 23 years, Sept. 14, 1914. Complaints of an eczematous eruption of nine months' duration on inner side of thighs, on hip and right armpit. Skin cracked and crusting. Serous oozing present. Cultures showed pure growth of staphylococcus aureus from which an autogenous vaccine was prepared. He received eight injections at intervals of from three days to two weeks. Eczema showed very marked improvement after first treatment and continued to improve steadily. Was given one further prophylactic treatment six weeks later and was discharged cured, Feb. 4, 1915.

VARIATIONS IN THE SENSORY THRESHOLD FOR FARADIC STIMULATION IN PSYCHOPATHIC SUBJECTS.

H. MANIC DEPRESSIVE INSANITY.*

By G. PHILIP GRABFIELD, M.D., BOSTON,

Interne, Psychopathic Hospital, Boston; Student, Harvard Medical School, Boston, Mass.

THE purpose of this study is to follow further the evidence obtained in a former series¹ of cases in regard to the sensory threshold for faradic stimulation in the manic-depressive group. In the former paper the following conclusion was drawn from the evidence then available: "The manic phase of manic-depressive insanity shows a normal threshold, the depressive a pathologically high threshold. One case observed at intervals for two years seems to show a high threshold ranging down to normal with the variations of his depression down to a normal emotional state." This conclusion has received ample confirmation in the present series of cases. The attempt has been made in this study to make further correlations in this group of cases. The question naturally arises as to whether this definite finding of a high threshold (diminished sensitivity) in depressed cases and of normal threshold (normal sensitivity) in the manic cases will throw any light on the nature of these psychic states.

As to the last point, many opinions have been advanced. In the 1913 edition of his text-book Kraepelin reviews at length his own and others' views, and finally arrives at the conclusion that all the clinical manifestations of this disease are but the results of a single pathological process. He feels that a very few basic changes combined in infinitely varying proportions make up this syndrome. He considers the chief cause to be a congenital psychic change and finds a definite "Anlage" of depressive, manic, and cyclothymic states in a large proportion of the Munich cases. As an explanation of the psychical "Anlagen," the hereditary factor is, of course, evoked, and is found by Kraepelin in over 80% of the cases. Thus he is certain that the personality is a marked factor in determining the type of the disease, and he explains the greater number of depressed states in late middle life as due to the further development of the personality at this time. He summarizes others' ideas as to the ultimate cause as follows. Meynert considers the cause to be an instability of the vasomotor center, especially in its control of the cerebral

vessels. According to this observer the depressions are due to cerebral anemia, the manic states to hyperemia. Lange, in 1896, advanced the idea of the similarity of this syndrome to certain periodic metabolic disorders, especially gout. Stegelmann found a diminished uric acid excretion during depressions. Pardo considered it an intoxication with the metabolic products of skin bacteria. He found an increase in the flora of the skin during the attacks, and more especially noted the appearance of a certain *coeco-bacillus* at this time. He also noted the fact that the attacks were often the sequel of dietetic errors, and that the attacks often terminated with a diarrhea. Parhon and Marbe lay the cause to the thyroid. Muratow to the adrenals, and Strasky to general metabolic disturbances. Anglade and Jaquin, following the lead pointed out by Morel and Doutrebente in epilepsy, state that in this disease as well as in epilepsy, the neuroglia presents an "infantile appearance," and also consider the cause to be congenital. Thalbitzer advances the theory that the cause is to be sought in a disturbance of the blood supply to Helweg's triangular tract. This is the outcome of the latter's observation of the frequency of lesions in this tract in this disease. Kraepelin finally states that "... the true cause of the disease is to be sought in lasting internal changes, which are perhaps always, at least very often, congenital." (p. 1369.) He also feels that according to this idea the symptoms of mania and depression are perhaps merely different degrees of the same process, and hence not so different as may appear. Yet Kraepelin insists that there is a definite pre-manic-depressive temperament for each of the forms. He finds that the depressive temperament may have superposed upon it attacks of mania without really altering the basic condition. He uses this as an argument in favor of his impression that the states of mania and depression are not so opposed as would be thought from a superficial examination of these states. Bresler² also considers mania and depression to be very nearly allied and expressions of the same fundamental process. He further states that they may be commingled in any case in infinitely varied proportions. As to this Kraepelin says: "Of greater significance than the construction of clinical pictures from certain underlying disturbances, is the realization that the disease forms here collected into a clinical entity not only run over into each other without recognizable boundaries, but that they may neutralize and destroy each other in the same case." Kraepelin includes in this disease the entire gamut of periodic and circular insanities, also what were formerly called simple manias, depressions and even some cases of dementia. He feels that the common basis of this disease is the prognosis; i.e., none ever end in deep dementia, even if the attacks are almost continuous throughout the lifetime of the individual. As to

NOTE.—I wish to express sincere thanks to Dr. E. E. Southard not only for the use of the clinical material, but also for his kindly cooperation and invaluable suggestions.

* Being Psychopathic Hospital Contributions Number 62 (1915-55). This paper was read in abstract at the March meeting of the Boston Society of Psychiatry and Neurology. (*Bibliographical Note*.—The previous contribution was by Donald Gregg, entitled "Somatic Characteristics of General Paralysis," published in the *Boston Med. and Surg. Journ.*, April 8, 1915.)

somatic findings, Kraepelin mentions the following observations. Paton found that manics made poor subjects for sensibility tests. Wolf-skehl found by using the tachistoscope that they could read correctly only 75% of the number of a series of letters which the normal person could grasp. Franz and Hamilton found the threshold for touch, pressure, and pain high in depressed patients. Aschaffenberg and Isserlin found the association time lengthened in patients who exhibited flight of ideas, but very much more so in depressed cases. Rehm, in investigating the capacity of the thought mechanism by its fatigue threshold, concluded that manic-depressives were on the average possessed of one-third less capacity than normal people, but that the manics were much better than the depressed cases. Kraepelin, in speaking of somatic delusions, says, "This increased sensitivity to the occurrences in their own bodies stands in vivid contrast to the depression of *central sensitivity* (italics mine) in manic states." Of course he here refers to objective central sensitivity. Thus we find that objectively the central sensitivity to stimuli from without appears by all previous investigations to be lowered in this disease, although less in the manic cases than in the depressed; that many theories of all kinds have been evoked to explain the disease, but that the factor of heredity seems to be the most prominent; that Kraepelin considers the cause to be an hereditary predisposition which is manifested in the personality of the individual. "Finally, we must consider the unapparent continuous changes in the mental life, which also appear in the intervals between the frank attacks as evidence of the *common psychopathological basis of manic-depressive insanity*" (p. 1237. Italics Kraepelin's³).

"We feel that the evidence to be presented will be of such a nature that it will rather support the idea that mania and depression are in reality different states or perhaps opposite perversion of function of the central nervous system, or perhaps of certain centers." (Southard and Bond—"Cells in Manic and Depressed States.")

The present paper deals with 66 observations on 25 cases chosen at random from those admitted to the Psychopathic Hospital. The diagnosis of manic-depressive insanity (which is made here according to the Kraepelin teaching) was in every case but two the final discharge diagnosis. The data obtained from this series are to be considered simply as a further note. The treatment in all cases consisted in rest, careful nursing, and hydrotherapy in the form of prolonged baths and moist warm packs. Even the manic cases with marked "leveling of ideas" made good subjects. In this series, as in the former, the only observations considered are those which were proved to be valid by constant trying and retrying of each position of the secondary coil of the inductorium. There were

only two cases which responded so irregularly that they could not be tested. These were both in the manic group, and both later gave valid results. There were a few cases that were so disturbed that they could not even be made to sit down in the chair to take the test and which were transferred to other institutions before they could be tested. There were also a few depressed cases that showed such a marked fear reaction that they could not be tested.

The method employed is the quantitative method of Martin,⁴ by which the "shocks" delivered by the secondary coil of an inductorium can be accurately measured in physiological units. The method depends on the fact that, with a primary current of known, constant strength, the shocks delivered by the secondary of an induction coil increase in strength as the secondary approaches the primary. A specially calibrated coil with the slide for the secondary graduated in millimeters, is employed. The patient dips his fingers (the index and middle fingers of the left hand) into two liquid electrodes (these consist of a mercury and calomel paste contact between the wires from the secondary of the coil and an overlying layer of salt solution), and is instructed to press a telegraph key whenever he feels a shock. The operator, who sits in a different room from the patient, cautiously approaches the primary coil with the secondary, a millimeter at a time. At each millimeter a key is pressed which short-circuits the "make" shocks and allows the "break" shocks to get through to the patient. Finally the patient signals, indicating that he has felt the shock. This point is tried and retried until the possibility of conscious or unconscious deception on the part of the patient is absolutely ruled out. This process is repeated with 10,000, 20,000 and 30,000 ohms resistance in the secondary circuit. Thus four independent readings of the position of the secondary of the coil with relation to the primary are obtained. The resistance of the coil itself is 2900 ohms. The resistance of the patient's skin is taken to be 2100 ohms. For work of the highest accuracy this resistance should be determined in every case, but it has been found that this resistance is a very constant figure, varying not more than 500 ohms to either side. From these data the value of the shock necessary to produce sensation may be calculated by certain formulae. The result is expressed in Beta units. For normal adults this threshold⁵ has been found to be in the neighborhood of 100 Beta units at its lowest point in the daily,^{6,7} variation. It varies from 60 to 160 at different times of the day and on different days of the week. One Beta unit is the average amount of shock required⁸ to cause a minimal contraction of a frog's gastrocnemius stimulated through the sciatic nerve in the well known nerve-muscle preparation. The threshold in this work has been expressed in Beta units throughout, and, of

course, the higher the value the less sensitive is the subject.

In the present series, consisting of 12 males and 13 females ranging in age from 18 to 67 years, all tests were made between 4 and 8 p.m., *i.e.*, at a time when the threshold is at its highest point in the diurnal variation.⁶

The results, as shown in tabular form, show the average of the 12 depressed cases to be 287 Beta units, a distinctly pathological value. This group consists in 44 observations ranging from 93 to 1661 Beta units. The latter enormous value was obtained in an alcoholic, and returned after a short time in the hospital to 400 Beta units, a not uncommon value for these cases. The only exceptions to the high threshold in this group were those cases which were tested at or very near the time of discharge. One case in particular is of interest as having been followed through two depressions. This case will be considered in greater detail later.

The average value of the threshold for the cases in the manic phase of the disease is 149 Beta units, a normal or slightly low value. This group consists of 22 observations on 13 patients. There were two exceptions to the universally low values obtained. One of these was considered clinically to be of the mixed type, perhaps one of the cases which Kraepelin considers to be periodic mania superposed on the depressive "Anlage." The other was undoubtedly a case of hypomania, but had a systolic blood pressure of 155 m.m. of mercury and a diastolic of 115, the latter being, according to Musser,⁹ almost pathognomonic of renal disease. This fact may account for the high threshold, as very high values have been found in the senile and arteriosclerotic psychoses. The lowest figure in this group was in an alcoholic with absent ankle jerks. Argyll-Robertson pupils, a negative Wassermann reaction in blood and spinal fluid on the day of his admission to the hospital. The last seems to be the significant point, as he was very euphoric. A few days later under hydrotherapeutic treatment he was much improved and his threshold was found to be 135 Beta units, as compared with the first value of 23 Beta units. With these exceptions, the manic cases were found to have a normal or slightly lowered threshold.

Those cases having definite hallucinations and delusions had a higher threshold than cases not showing these symptoms. It is evident that these cases averaged higher values than even the depressed cases. Of the cases showing one or both of these symptoms, 10 were in the depressed phase and nine were manic. As it is found that the manics showing the symptoms yield no values over 200 Beta units, *i.e.*, the manics showing these symptoms were high as compared with the other manic cases, but not high enough to come into the depressed group. The reason for the high averages is to be laid to the enormous thresholds shown by the depressed cases showing

TABLE I.

Total	25	12	13	23-1661	66	237

this symptom. To be sure, the manic cases showing these symptoms yielded readings which were at the upper limits of the normal range, and perhaps at times a little beyond. The fact that the readings in this group varied so greatly among themselves makes this conclusion of less value than would appear.

Other correlations (blood pressure, reflexes, usual sensory tests, tremors, cyanosis, etc.) were attempted but yielded no results. Other than those mentioned as alcoholic there were no cases who used any drugs. With the exception of the above-mentioned case, none showed any reflex disturbance or other neurological signs.

The prognostic value of this test in depressed cases is well illustrated by the case which has been cited before,¹ and which may be repeated here in greater detail. A piano tuner of 56 years of age was first seen in July, 1912. At this time he complained of inability to do his work and more especially of his lack of interest in things which formerly interested him, and of inability to get started at anything. At this time he was found to have a threshold of 318 Beta units. As the depression gradually wore off in the course of the next three weeks values of 219 and 163 Beta units were obtained, and finally, after a short vacation, his threshold fell to 106 Beta units. From this time on he felt perfectly well until May, 1914, when he returned feeling that another attack was approaching. At this time his threshold was 227 Beta units. He was advised to take a vacation immediately, which he did. In the course of the summer he wrote that he was steadily improving. He was again seen after he had been at work for a month. He was seen on a Saturday at 5 p.m., after a week's hard work. At this time he stated that he was feeling perfectly well. His threshold was 197 Beta units, a normal value for this time of the day⁶ and day of the week.⁸ The other depressed cases that have been followed to recovery have shown the same thing, though in a less striking way, because the others have been

true depressions rather than cases of "simple retardations." It is unfortunate that the manic cases cannot be followed as completely as can the depressed cases.² Thus it will be seen that one practical application of this test will be to determine when a depression ends, or rather to give us a means of determining by a numerical standard whether a patient has improved or is getting worse.

The application of this test as a point in the differential diagnosis of manic-depressive insanity will certainly be possible. That the differentiation of true depressions of this psychosis from those of the psychoneurotic group will be made vastly easier by the determination of this threshold is definitely indicated by the evidence which is at present available. In this psychosis the threshold is always raised in depressed states, whereas in the psychoneurotic group of cases it has been found to be within normal limits.¹ Thus we feel that the determination of this threshold will give information not only of prognostic, but also of diagnostic value, as far as can be determined from the evidence now available.

From this group of cases there has been accumulated evidence to show that the sensitivity of individuals suffering from manic depressive insanity to faradic stimulation is increased to a pathological point during the depressed phase and is normal or slightly decreased during the manic phase. It is a significant fact (and it is on it that the suggestion is based that the manic forms may have a slightly lowered threshold) that the manic forms yielded slightly more results under 115 Beta units than would a series of normal individuals at this time of day. This finding is also in accord with the view suggested by Southard,¹⁰ that hyperkinesis and allied states are associated with a "tissue-simplification," perhaps due to a withdrawal of the cortico-thalamic "inhibitory" or "switch-setting" impulses. Bevan Lewis has found an absence of metabolic pigment in hyperkinetic states, and Southard and Bond¹¹ have shown an increase of metabolic or catabolic lipid substances in depressed cases of manic-depressive insanity. That the latter finding may be correlated with a "tissue-complication," as the former has been correlated with a "tissue-simplification" is not improbable. With the histo-pathological evidence which Southard has reported, it is perhaps, not wrong to consider these variations in the sensory threshold as evidence of a functional hyper- or hypotonicity of these or similar centres, brought about, perhaps, by disturbances in cell metabolism. That this threshold appears to be a valid index of the condition of the "tone" of the central nervous system is also supported by the observation that the variations in normal subjects⁹ correspond to certain variations of central nervous system "tone," as determined by other observers and by different methods.

It is, furthermore, found that four-fifths of

these cases at necropsy show no gross brain lesions, and that the remaining fifth show lesions similar to those found in dementia precox,^{12, 13} plus a slight grade of internal hydrocephalus. It seems as though this evidence from the anatomical point of view, taken in conjunction with that gained from the physiological, makes very probable the existence of variations in the functional activity of the central nervous system or of its parts as the basis of the variations of the emotional tone in manic-depressive insanity. From this point of view it seems as though Kraepelin's "Anlagen" may turn out to be congenital susceptibility to variations in tone rather than variations of an anatomical nature.

In conclusion, it is to be emphasized that in our opinion the evidence here presented points very strongly in the direction that manic-depressive insanity is a result of deranged function, and that the pathological physiology of the central nervous system in this psychosis deserves further study, especially as to whether the states of mania and depression may not be due to opposite perversions of function.

SUMMARY.

1. Twenty-five cases* of manic-depressive insanity have been selected at random from the clinic of the Psychopathic Hospital, Boston, in order to follow further the results obtained in this group of mental diseases in a former orientation study.

2. The present series has confirmed the impression gleaned from the first series of psychopathic cases.

3. The method employed is that devised by E. G. Martin for the measurement of induction shocks.

4. The cases in the depressed phase show a decided raising of this threshold to definitely pathological values.

5. This increase in the depressed cases falls to normal with the return to a normal emotional state.

6. The cases in the manic phase show a normal or perhaps slightly lowered value for this threshold.

7. The cases with hallucinations or delusions or both show when averaged a markedly higher threshold than the average of even the depressed cases. The average is obscured by the fact that it contains many nearly normal values obtained in manic cases. These symptoms, however, seem to indicate a more profound derangement of function, as the cases, whether manic or depressed, which showed them yielded the highest values in the group in which these cases fell.

8. The impression that variations in the sensory threshold for faradic stimulation are of central origin (derived from work on normal subjects) seems to be borne out by this group.

* The case numbers are: 2165, 4291, 3709, 1901, 3872, 3700, 11, 3860, 3886, 4228, 3734, 3585, 2057, 3837, 3687, 3896, 1764, 2153, 3640, 3895, 1970, 3862, 1868, and two cases, referred to me by Dr. E. E. Southard, which were not hospital cases.

9. The suggestion is made that the manic-depressive syndrome may be due to a perversion of function of certain parts of the central nervous system, possibly the thalamic centres, and that, contrary to Kraepelin's view, the symptoms of mania and depression may be due to opposite perversions of function.

VARIATIONS IN THE SENSORY THRESHOLD FOR FARADIC STIMULATION IN PSYCHOPATHIC SUBJECTS.*

III. THE DEMENTIA PRECOX GROUP.

By G. P. GRABFIELD, M.D., BOSTON.

Interne at the Psychopathic Hospital, Boston.

THE present paper deals with 51 cases diagnosed dementia precox, at the clinic of the Psychopathic Hospital, Boston, on which the sensory threshold for faradic stimulation has been determined by the Martin method.³ In the first work done with this method in this clinic the results in this group were surprisingly clean cut

* I wish to express my sincerest thanks to Dr. E. E. Southard for placing the clinical material at my disposal and for his invaluable help in reporting the results especially in suggesting the significant correlations.

³Being Psychopathic Hospital Contributions Whole Number 69 (1915-6). (*Bibliographical Note*). The previous contribution was by G. P. Grabfield (1915-5), entitled "Variations in the Sensory Threshold for Faradic Stimulation in Psychopathic Subjects: II. Manic-Depressive Insanity," published in this issue of the *Boston Med. and Surg. Jour.*, page 195.)

and the following conclusion was drawn from a series of 135 cases of mental disease (21 cases of dementia precox¹): "Interesting figures are available for cases of dementia precox, indicating that the paranoid forms have a normal threshold, whereas those classed as catatonic and hebephrenic have pathologically high thresholds. It is remarkable that the hebephrenic cases tested (two in number) showed some of the highest thresholds calculable (760). Eight catatonic cases averaged 232 (paranoid 131).² These remarkably concordant results have not been borne out by further study of this group.

That this series should not afford results which, by a test which has so far proved physiologically valid, are of diagnostic value, is not surprising when one takes into consideration the polyglot character of dementia precox as described by Kraepelin.⁹ Furthermore, we are dealing here with the group in which the margin of error of the Psychopathic Hospital diagnoses is the largest—as judged by the further progress of the cases at the state institutions to which they are sent. This error is about 20%,⁴ and its size may be due in part to the fact that the other hospitals do not follow so strict a Kraepelinian grouping as is the case here. However, the very irregularity of the results will have some value as diagnostic evidence, and certain interesting observations as to the pathological physiology of dementia precox have been made. As to the latter, the more important deal with emotional tone and catatonic symptoms.

The method employed is that of Martin,³ slightly modified as described in a former paper. The results are expressed in beta units, which are units of "shock" given. In using this method of notation the higher the value the less sensitive is the subject tested. The material consists of 90 observations on 51 patients. Of these 90 observations three proved to be invalid, due to lack of coöperation on the part of the patient tested. These were on different patients who at some other time yielded a valid result.

The lack of correspondence between the clinical observation of emotional tone and the sensory threshold for faradism is the most striking feature of this series (*cf.* Table I). This observation is the more remarkable in contrast to the results obtained in the manic-depressive syndrome (*cf.* Figure), where the depression was a distinct factor in raising the threshold. In this group an explanation for this was suggested² which was based on the histopathological evidence adduced by Southard⁵ and Bevan Lewis (quoted by E. E. Southard⁶). It was suggested that the maniacal states of manic-depressive insanity might be associated with a "tissue-simplification," affecting among others the receptor system, and that the depressed states might, on the contrary, be associated with a "tissue-complication" affecting this same system. Obviously, this cannot be true of the dementia precox group, and we are forced to the conclusion that the emotional tone in dementia precox is

TABLE I.

Type.	No. Cases.	Male.	Female.	No. of Observations.	Limits of Variation.	Average Threshold.
Manic	12	10	2	16	61—777	187 <i>B</i> units
Depressed	30	20	10	52—3=49	72—743	186 "
Normal	9	6	3	22	73—518	188 "
Total	51	36	15	90—3=87	61—777	186 "

governed by a different mechanism than that which governs this process in manic-depressive insanity.

It is unfortunate that no definite results of diagnostic value have been brought out by this study. Of the entire series of 51 cases only 33% constantly yielded pathological values (over 175 beta units). Forty-eight per cent. showed a pathologically high threshold at some time. Thus 52% are found who have never shown anything but a normal threshold value, and 67% showed a normal value at some time. There were 21 cases who had more than one valid test made upon them. Of these cases only 9 (43%) showed at some time a pathological value. Although this group is not large, a consideration

values within the various groups makes it unlikely that this test will be of use in this direction.

In the consideration of this test from the viewpoint of differential diagnosis, one impression may be of value. Certain of the cases on repeated tests showed remarkable changes in the values obtained. This was more apparent the oftener the cases were tested. The interesting point about these changes was that they did not seem to follow any fixed rule nor were they capable of correlation with any clinical observation of the condition of the patient. In all other groups studied the values on repeated observation remained about the same or varied as the clinical picture varied. The only group in which anything similar has been observed is the Korsakoff cases. The data at present available on this point are very meagre, but it seems to be a line of investigation worth following.

A consideration of the cases showing a threshold value of over 200 Beta units at some observation (*cf.* Table II) brings out the fact that a very large fraction of these cases show symptoms of catatonia and somatic delusions. Fifteen such cases were found and of these 67% showed catatonic symptoms and 47% showed somatic delusions. Certain authorities¹⁰ deny the possibility of dementia precox without hallucinations. From two cases in this group no hallucinations were elicited. One case (No. 19263958) was markedly alcoholic, and it is probable that his hallucinations were due to alcohol. If these three cases are omitted from consideration, we are left with 12 cases in which the diagnosis of dementia precox is highly probable and who at some time showed a threshold value of over 200 beta units. Of these 12 cases, 67% showed symptoms of catatonia and 42% showed some somatic delusions. Southard^{6, 7} has correlated the symptoms of catatonia with post-rolandic cortical lesions, *i.e.* lesions in the sensory "arrival-platforms." He has also advanced the view, from evidence obtained at necropsy, that somatic delusions have their basis in fact perverted possibly by a disturbance of the receptor mechanism.⁸ The parallelism between these symptoms and high sensory thresholds, in view of the post-mortem findings, is suggestive.

A consideration of the cases showing at some observation a threshold value under 100 beta units revealed a remarkable dearth of catatonic symptoms and somatic delusions (*cf.* Table III). Nine such cases were found. Of these, 33%

of the above figures seems to make it justifiable to conclude that only about 50% of the dementia precox cases show a pathologically high threshold, even when tested more than once. In this connection, it is to be remembered that the cases passing through this clinic are as a rule not far advanced.

As to the value of the test in differentiating the types of dementia precox, as described by Kraepelin, the evidence at hand is not very satisfactory. However, the large variation of the

showed symptoms of catatonia and 11% showed somatic delusions, and 22% showed delusions which may possibly be classed as somatic. Eliminating from this group the cases from whom no hallucinations could be elicited and one case (No. 3583) whose hallucinations were

probably due to alcohol, we are left with six cases in which the diagnosis of dementia precox is highly probable and of which 17% (1 case) showed catatonic symptoms and these only of the vaguest kind. Seventeen per cent. showed somatic delusions and 33% showed delusions of

a vaguely somatic character. One of the cases excluded was a case of dementia precox which all agreed was of the catatonic form, and the stupor in which this case was throughout his stay in the hospital (No. 2121) may account for the failure to elicit either hallucinations or delusions. Thus in the group showing a low threshold value we find that only 17%-33% showed symptoms of catatonia and 11%-50% showed somatic delusions.

No relation could be traced with hallucinations nor with the various types of hallucinations (*cf.* Table IV). Delusions other than somatic were so variously designated that it did not appear feasible to record the types of this symptom as mentioned. Other than the somatic before mentioned, there appears to be no relation between the presence of delusions and the threshold value.

We have, then, found in a series of 51 cases* diagnosed dementia precox, that the sensory threshold for faradism quantitatively measured does not afford results of diagnostic value in nearly two-thirds of the cases, that the concordant results of the first group of cases studied in this way are not sustained by this series, that the parallelism between high threshold values and catatonic symptoms and somatic delusions is suggestive in view of the evidence in regard to these symptoms, which has been found post mortem, that the correlation between the lowest threshold values and lack of these symptoms strongly supports the previous correlation, that the types of hallucinations and delusions (other than somatic) could not be connected with the threshold values, and finally that the irregular variations of cases repeatedly tested may have a significance diagnostic or otherwise which would be worth investigating. In conclusion, it is again to be noted that, even though the results of this series have not lead to conclusions of diagnostic value, certain observations as to the pathological physiology of the central nervous system in dementia precox have been afforded by the quantitative determination of the sensory threshold for faradism.

CONCLUSIONS.

1. The determination of the sensory threshold for faradism shows that pathological values are constantly obtained in only about one-third of the cases of dementia precox and hence that this determination is of diagnostic value only in this percentage of cases.

2. The mechanism governing emotional tone in dementia precox appears by this test to be different from that which governs this phenomenon in manic-depressive insanity.

3. The correlation of catatonic symptoms with high threshold values parallels the correlation between these symptoms and post-rolandic cortical lesions. From this it is probable that the "arrival platforms" for faradic stimuli lie in the post-rolandic region.

4. The correlation between somatic delusions and high threshold values is evidence in favor of the suggestion that these delusions are associated with a perversion of the receptor mechanism.

Reports of Societies.

CLINICAL CONFERENCE OF THE NEUROLOGICAL INSTITUTE, NEW YORK.

REGULAR MEETING, APRIL 22, 1915.

DR. J. RAMSAY HUNT, in the Chair.

GLIOMA OF FRONTAL LOBE, WITH NOTES ON ASPIRATION OF THE BRAIN FOR DIAGNOSTIC PURPOSES.

DR. PEARCE BAILEY AND DR. CHARLES A. ELSBERG presented the following case as a contribution to the symptomatology of frontal tumors, and also because positive diagnosis as to the approximate site and exact nature of the tumor was established during life.

A civil engineer, aged 50, had been actively engaged in his profession until Feb. 1, 1915. At that time, when called upon to give an expert opinion regarding bridge building before a commission, he was unable to express himself in a way that the commission could understand him and was released as a witness. A few days after this, he awoke early one morning with an attack of vomiting. At about the same time he began to complain of dull pain through the centre and base of the head. Up to this time he had been a perfectly healthy and normal man, but from this time onward he became more and more incapacitated, largely by reason of his mental symptoms.

Mental Symptoms. These in the first instance consisted in the so-called Witzelsucht. He would burst out laughing when the simplest question was put to him, and if he tried to answer it, the answer would be accompanied with explosive laughter. He also became very profane in his remarks, which was quite contrary to his previous custom. Associated with this condition was a certain amount of hebeteude, which deepened as the case progressed. At first he would be merely inattentive and not particularly talkative, but later he would sit for hours without paying attention to what went on about him and without volunteering any remarks at all. He gave up reading almost altogether, although he could read, could understand what he read, could write, and had no definite symptoms of aphasia, although he occasionally made a misuse of words. There was no apraxia. An indication of the mental hebeteude was furnished early in the disease, by lack of care of his person. He would void urine in his clothes or in bed and would make no effort to remedy or call attention to the accident. Later in the disease, on several occasions there was the same trouble with the bowels. These disturbances were not the result of any sphincter trouble.

Eye Symptoms. The only trouble with the ocular apparatus was a slight swelling of both discs, mostly on the right side. This was hardly enough to merit the term "papillitis," and increased only moderately while he was under observation. The direct compression symptoms described by Kennedy in regard to frontal tumors was absent.

Other Cranial Nerves. The cranial nerves were normal with the exception of a slight weakness of the left face and a slight deviation of the tongue to the left. These were never pronounced, and if they had not both been on the same side might almost have passed as normal physiological variations.

Motor Symptoms. With the exception of the

anomalies of the face and tongue, just mentioned, there were no motor disturbances. There were no paralysis, no tremors, no incoördination. Patient could walk, use his hands, and retained his strength.

Reflexes. The deep reflexes presented strange anomalies. At times the knee jerks would be almost absent, and at other times hyper-active, without any apparent cause to account for these changes. At one time the left Achilles jerk disappeared, to return again and become normal.

X-ray Findings. A large number of radiographs were taken of the skull and of the cranial sinuses, without revealing any facts which had bearing on the cerebral condition.

Serological Examinations. Both blood and cerebrospinal fluid were negative to the Wassermann reaction, the former was also negative after a provocative Wassermann test. The cerebrospinal fluid contained 16 cells and an excess in globulin.

Clinical Evolution. Before the operation, the patient was under observation about five weeks. During this time there was a progressive involvement of mentality, so that the original Witzelsucht merged into a general condition of hebeteude. There was no persistent vomiting, but toward the end of the period of observation the patient vomited several times. The carelessness about his person increased. It was difficult to tell whether or not he suffered pain, as he did not express himself freely, but the nurses thought that at times he had considerable headache. The only evidence of increase in intracranial pressure was a slight increase in the swelling of the optic nerves.

Diagnosis. The patient was running down hill so persistently that it became necessary to determine promptly the nature and position of the disturbance, which was plainly intra-cranial. The absence of any specific disease or of any vascular disease, made a diagnosis of localized intra-cranial trouble almost certain, and the predominating mental character of the symptoms, the practical absence of all other symptoms referable to focal regions, seemed to indicate the frontal lobes as the seat of the disturbance, although it was impossible to tell on which side of the brain the disturbance was. The choice as to the nature of the disturbance seemed to lie between an abscess and tumor, and to determine these two points, which could hardly have been determined in any other way than by exploration, exploratory interference was undertaken.

SURGICAL NOTES.

DR. ELSBERG: We considered it advisable to do an exploratory puncture over both frontal lobes, rather than in the beginning to do a large exploratory operation. Inasmuch as it was impossible to say with certainty whether the disease was in the right or left frontal lobe, we determined to aspirate these regions for diagnostic purposes. The typical Neisser puncture we considered inadvisable because of the danger of injury to the pial vessels. The following procedure was, therefore, adopted:

Under ether anesthesia and through a small incision over the right frontal lobe a button of bone was removed, a small incision in the dura made and the frontal lobe punctured in several directions. No fluid was obtained; the small cylinders of brain tissue obtained were preserved for microscopical examination. The same procedure was repeated on the left side. The brain tissue obtained from the right side was of very soft consistency, while that of the left was much more firm. The buttons of bone

were returned into place and the small scalp wounds sutured.

The patient recovered from the operation without incident.

The pathological report was: Tissue from the right frontal lobe—normal; tissue from the depth of the left frontal lobe—glioma of the infiltrating type.

REMARKS.

By this simple procedure, it was possible to make the diagnosis of irremovable tumor of the left frontal lobe and to save the patient a more extensive operative procedure. I have made use of this procedure in a number of instances and have found it of the greatest value. As above stated, I consider the Neisser puncture dangerous, but the method here described is practically non-dangerous, because through the small opening in the skull and dura a portion of the brain free from blood vessels can be selected for the puncture. By this method of diagnosis it is possible to locate an otherwise unlocalized growth and to determine the nature of that growth or to discover the location of an abscess. The microscopical examination of the small cylinders of brain tissue removed by the needle will tell one not only whether disease is present, but the nature of that disease, and in a number of instances I have been able to find the disease, to determine its nature and to come to the correct conclusion as to its operability by this method. I have been able to save unnecessary and useless operative procedures, and, on the other hand, have made more certain my indications for operative interference in removable growths. The method deserves far more extensive use than it has had heretofore.

CASE OF CHRONIC PROGRESSIVE CEREBELLAR TREMOR WITH ARGYLL-ROBERTSON PUPILS.

DR. HENRY K. MARKS presented from the First Division the case of a tailor, married, 67 years old. His family history is quite negative. At the age of eleven he had a traumatic infection of the left hand. About the same time there occurred what was apparently an osteomyelitic affection of the right shin, which persisted for a number of years. At the age of 22 he contracted gonorrhea. Syphilis is denied. His wife, a healthy woman, has been childless. There have been no miscarriages.

Always a temperate man, he enjoyed excellent health, never missing a day's work up to twelve or thirteen years ago. From this time dates his present illness. While riding to his work one morning, without premonitory symptoms of any sort, he suddenly felt a sharp, stinging blow just beneath the occiput. He was dazed, perhaps even unconscious for a few seconds, fell back in his seat and was unable to articulate distinctly. Friends supported him to his shop. He walked as if drunk, reeling from side to side. The following day he went to work as usual. He felt rather weak but his gait was now natural. He noticed, however, that his speech was disturbed, stuttering as he described it, but without any aphasic element. This cleared up entirely within a couple of days.

The next two weeks, except for an indefinite feeling of weakness and an occasional mild dizzy attack, were uneventful. Then he noticed that his hands, particularly the right hand, were beginning to grow unsteady, to shake while at work. The tremor, slight at first, has since then slowly but

steadily increased, occurring at rest, though to a much less extent as well as on movement. Up to a month ago, however, he was still able to thread a needle and sew.

Other symptoms which have appeared since the onset of the illness are an alteration of his speech, first becoming noticeable a few months after the appearance of the tremor; a shaking of the head of four or five years' duration; a weakness of his legs of one year's duration to which shakiness, as on stooping, has been added during the past three months. All these symptoms have shown a slow, gradual progressive course.

In his boyhood he suffered from periodic headaches of a migraine type, but since the age of fourteen or fifteen he has been quite free from headaches of any sort. For the past year or so he has had an occasional mild attack of dizziness. His memory shows no gross impairment; for two years or so, however, he has had less emotional control. His special senses—eyesight, hearing, etc., have not been affected. His general health is very fair. He eats and sleeps well and has good sphincter control.

Physical Examination. The patient is a short, stocky man of flabby musculature. His serum Wassermann is negative. His blood pressure is 160; his urine shows a trace of sugar. Otherwise general examination reveals nothing noteworthy.

His pupils are pin point in size, the left slightly greater than the right. They give no reaction to light, but converge well on accommodation. Ocular movements upward and downward are, perhaps, somewhat restricted. Other abnormalities are lacking. He shows defective voluntary control over the corrugator and frontalis muscles, the left angle of the mouth sags a little, but there is no definite evidence of seventh nerve involvement. His tongue is protruded straight, is tremulous and shows a tendency to be drawn in and out of the mouth. Otherwise the cranial nerves are negative.

His musculature is flabby, range of movement in all the joints except for traumatic restriction of the left index finger, is normal. There is no hypertonia. Power is very fair, quite proportionate to the muscular development.

His arm reflexes are present, equal; his knee jerks active, the right slightly greater than the left; the ankle jerks are present and equal. Plantar stimulation gives a flexor response, Babinski, Oppenheim and clonus are absent. The epigastric and abdominal reflexes are present, though sluggish. Sensation both superficial and deep, shows no disturbance, whatever.

A casual glance at the patient reveals his striking and essential characteristics. I refer to a constraint, a fixity of his facial and body expressions and to his tremor. His face has a mask-like quality, his head is lightly flexed on his chest, his shoulders stooped. He carries his limbs close to his body. His movements are all slow.

Standing, his whole body is seen to be agitated by a tremor. His head nods, his lips tremble, his arms show an up-and-down excursion from the shoulders, his chest and abdomen show a fine longitudinal movement, with something of a rotatory character added and a slight tremor occurs in the legs, especially in the region of the knees. The oscillations are not continuous nor perfectly rhythmic, and vary from 80 to 140 per minute. At times, when the patient is perfectly quiet and does not feel himself observed, the tremor may practically disappear. It is increased by exertion and

emotion. Sitting tends to decrease the tremor and lying down even more so.

The hands with arms at rest usually tend to assume the pill rolling attitude, but the tremor itself is, as a rule, slight. With the arms outstretched a coarse longitudinal and rotatory tremor of the hands occurs, which is even further increased on raising the arms above the head. The right arm is somewhat more affected than the left. Initial movement tends to decrease or even to stop the tremor, sustained effort to increase it. In the finger-nose test we detect no ataxia, no dysmetria in the sense of over-reaching, but a tremor of the intentional type. It begins toward the close of the act and becomes so marked and intense that a sustained position is impossible. Alternating movements are slowly and clumsily performed and the rhythm is quickly lost. In the legs slight oscillations occasionally occur toward the close of the heel-knee test. Ataxia dysmetria and asynergia are absent.

There is no Rombergism in the strict sense. Instability increases on closing the eyes, but this is apparently due to increases of the tremor.

The patient's gait is somewhat broad based with a slight waddling tendency. It is not of the *petit pas* type nor propulsive. His vertebral column is rather rigid as a whole.

REMARKS.

We have, then, the history of a slow progressive tremor of thirteen or fourteen years' duration. General symptoms of cerebral disease are absent, likewise symptoms referable to the vestibule apparatus. How are we to regard this case? Obviously there are certain superficial resemblances to Parkinson's disease. Various objections may be raised; the mode of onset of the disease, the absence of muscle hypertonia, the fact that the tremor at rest is least marked or may be wanting altogether while it is invariably increased under dynamic conditions, that tremor of the intentional type is present, that the gait is in no wise characteristic. Granted that these deviations may be regarded singly as merely atypical and granted that all of them may have been recorded in cases considered Parkinson's disease, still in their totality they are significant. The suspicion against Parkinson's disease is further increased by the Argyll-Robertson pupil.

Our knowledge of the pathology of paralysis agitans is still too obscure to allow us to venture an assertion as to the seat of the disease. The recent work of Wilson on progressive lenticular degeneration has turned the attention again to the basal ganglia. But the basal ganglia have an intimate connection with the cerebellar tracts. On this hypothesis it is unreasonable to suppose that a disease process interrupting these connections will not produce a disease picture resembling more or less Parkinson's syndrome? In other words, have we not to do in this case with a lesion somewhere along these connecting tracts?

The patient as I conceive it is a syphilitic. The sharp stinging blow he felt in the occiput thirteen years ago was a vascular accident, probably a thrombus occurring on a syphilitic basis in the cerebellum. The initial symptoms, you may remember, were slow stuttering speech and a reeling gait. The symptoms were short-lived followed by the group above recorded. Among them we may still find a cerebellar component in the tremor of

the intentional type, the broad-based gait with its suggestion of reeling, the slowness and awkwardness of alternating movements, the slow and labored speech. Whether the lesion be an inflammatory one or a bilateral systemic one, as in posterior column degeneration, which seems the more probable, we cannot, of course, definitely say.

In many of its aspects, the case resembles a type of progressive cerebellar tremor described by Dr. Ramsay Hunt (Brain, 1915). This affection is characterized by the gradual progressive development of intention tremor, associated with dysynergia, dysmetria, asthenia of intermittent character and slight hypotonia. (The dysynergia cerebellaris progressive.)

INTENTION TREMOR OF THE LEFT ARM ASSOCIATED WITH CHOREIFORM MOVEMENTS, DEVELOPING DURING PREGNANCY.

DR. ROBERT E. POU presented from the Second Division, an American Jewess, thirty years of age, with the following history: She was entirely free of her present affection until her 27th year, and with the exception of measles, gave no history of previous disease. Menses began in her thirteenth year, stopped until the seventeenth, and since then have been normal. A search into the family history reveals nothing of importance, except the fact that she has a brother 35 years old who was always weak-minded, and who has been in the Manhattan State Hospital since his nineteenth year. At that place he is considered an imbecile, and is declared to be free of any physical neurological symptoms. About the age of 21 the patient contracted an illicit union with a man to whom she bore two "instrumental" children. The first of these, born six years ago, died at the age of six weeks, probably of tuberculosis. The second is a healthy boy of five years. During her second pregnancy, the patient received an accidental blow in the small of her back, which, however, did not interrupt the pregnancy, and was not followed by any untoward symptoms.

The present illness dates back three years, when the patient noticed the gradual onset of cramping, aching pains in her left arm, not constant, but coming on every three or four hours, and lasting for a few minutes at a time. After two or three weeks of these pains she began to have involuntary movements in the left arm and hand, increased by purposive motion. She went to the Lying-in Hospital, where a diagnosis of acute chorea was made. She now felt tingling sensations in her left face, arm, trunk and leg, accompanied by a subjective weakness in the left side.

The patient was sent to the Neurological Institute at this time, being then in the fourth month of pregnancy. She showed a peculiar, rhythmical, choreiform tremor of the left arm and hand, made distinctly worse by efforts to coördinate. This tremor was accompanied by a choreiform twitching of the mouth, and a hesitating, explosive speech. The right hand and arm were normal. Knee jerks and ankle jerks were equal on the two sides. There was a suggestion of hypaesthesia in the left side, but the meager intelligence of the patient left this in doubt. Dr. Holden found the pupillary reaction good in a bright light, but sluggish when the light was thrown in by a mirror. The pupils were equal, the mobility of the eyes was normal, and the vision as well. There was no nystagmus, and the fundi were normal. Excessive concentric contraction of the color-fields was noted, and at times, unocular

diplopia. The left cornea was slightly anaesthetic. Dr. Holden thought the findings suggested hysteria. The Wassermann was negative.

The patient returned to the Lying-in Hospital in May, 1912, where her uterus was emptied of a macerated fetus, the age of which was not estimated. A blood count showed 4,240,000 red cells, 80% haemoglobin. Numerical white blood count not made. Differential white count normal.

Within the last three years the patient has been seen regularly at the Institute, and her condition has undergone but little change, except an additional tremor of the right hand, seen only at times, and never increased by purposive movement. She also complains at times of "sticking" sensations in the right arm. A year ago she was married to the father of her children, and has since had two inevitable abortions at about the third month of pregnancy.

A recent examination reveals a small, pale, undernourished woman, thin almost to the point of emaciation. She walks with a peculiar, somewhat choreiform gait, and shows a coarse, bilateral tremor of the arms and hands, much more marked on the left side. The right hand can be well coordinated, but the left tremor is greatly increased by purposive motion. Much of the time the right-handed tremor is not seen, but that of the left arm and hand is constant except during sleep, when all the tremors cease. It is fairly rhythmical, about three to the second, and so continuous that the patient tries to overcome it by grasping the left hand between her knees, or holding it with her right. Combined with these tremors of the hands is a choreiform movement of the mouth, while her speech is hesitating and explosive. In the recumbent posture a fairly constant choreiform movement is seen in both feet, and associated movements are easily elicited.

There is no evidence of unilateral weakness of arm or leg, but a suspicion of weakness in the left face is noted. Adiadokokinesis in both arms. No fibrillations, no nystagmus.

The deep reflexes are generally increased, the right knee jerk being slightly more marked than the left. A moderate clonus, seen in both feet, is quickly exhaustible.

Among the skin reflexes the epigastries can be only faintly elicited, the abdominals not at all. As to the plantar reflexes, it is difficult to decide, as the reaction is obscured by the choreiform movement of the toes. While the Babinsky reaction is uncertain, there is a fairly constant Oppenheim and Gordon, and a crossed extensor reflex is occasionally seen in the right big toe.

Dr. Holden finds the eyes about as they were three years ago: Vision and fundi normal; marked centric contraction of the color-fields, and at times, a uni-ocular diplopia. Pupils slightly sluggish to reflected light, but react promptly to a bright one.

Pharyngeal reflex normal. With the exceptions above noted, the cranial nerves are normal.

There are no sensory changes, no astereognosis. The back is flexible, and not tender, there are no deformities, no trophic disturbances, no change of tonus, no mechanical restrictions. There is no change in emotional innervation of the facial muscles; and, while the patient is apt to weep at the recital of her domestic wrongs, there is no forced crying or laughter.

Dr. Kaplan finds a positive Wassermann reaction in the blood. The spinal fluid is negative.

Heart and lungs negative.

The posterior cervical chain of glands is distinctly felt, small and "shotty."

REMARKS.

This case has been thought to be of interest because of the somewhat atypical character; the peculiar tremor, the intentional element of which is wholly confined to the left arm, where it is very marked; its non-progressive course; the absence of definite remissions; and in sum, its difficulty of diagnosis. The nature of the onset and the probable existence of lues strongly suggest a vascular lesion of syphilitic nature, located somewhere in the cerebello-rubro-spinal tract.

Oppenheim reviews the subject somewhat as follows: Hemichorea and hemiathetosis have so often followed lesions of the optic thalamus that they were at one time assigned to that region. On the other hand, experience seems to prove that not alone lesions of the pulvinar, but excitations of the neighboring pyramidal tract are responsible for the phenomena. Eventually the hypothesis was advanced that affections of the motor cortex and lesions in close proximity to the motor tracts also gave rise to these symptoms. Charcot and Raymond found the lesion in one case in the internal capsule. The followers of Kahler and Pick, however, attribute the phenomena of hemichorea and hemiathetosis to lesions of the central thalamic nucleus, the lenticular nucleus, the sub-thalamic region, the red nucleus, the anterior cerebellar peduncle and cerebellum. Monakow conceives in such cases a continuous excitation in the thalamus and mid-brain of those centripetal fibers whose destination is the motor cortex. Anton suggests an antagonism between the optic thalamus and lenticular nucleus, and ascribes to the latter body an inhibitory influence on automatic movements. Destructive lesions of the lenticular nucleus and its outgoing inhibitory tract would, therefore, allow the untrammelled play of involuntary impulses from the thalamus. Bonhöffer and others locate the causative lesion among those fibers which pass from the cerebellum to the thalamus by way of the brachium conjunctivum, and then to the cerebral cortex. Some observers modify Bonhöffer's theory by raising the question whether the phenomenon be one of stimulation or destruction of the tract. Halban and Infield seek to reconcile the theories of Anton and Bonhöffer. Wilson and C. Vogt have both reached the conclusion that the corpus striatum exercises an inhibitory influence upon the cortico-spinal tracts, and that it does so through the medium of the lenticulo-rubro-spinal system.

Oppenheim himself sums up as follows: Such post-hemiplegic results as hemichorea and hemiathetosis may be called forth by direct or reflex excitation of the automatic motor centers in the optic thalamus.

1. By small lesions which lie in the thalamus and act as excitants.

2. By the injury to those sensory fibres which pass from the cerebellum to the thalamus by way of the brachium conjunctivum.

3. By interruption of inhibitory impulses passing out of the corpus striatum and lenticular nucleus.

4. By cerebral accidents of childhood which damage the motor cortex, thus bestowing an unwanted freedom upon the involuntary motor centers in the thalamus.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

MEETING OF WEDNESDAY, APRIL 7, 1915, AT 8 P.M.

The President, DR. JAMES C. WILSON, in the Chair.

SARCOMATOUS DEGENERATION OF A FIBROMA OF THE UTERUS FIVE YEARS AFTER X-RAY TREATMENT FOR PRESSURE AND HEMORRHAGE.

DR. GEORGE EREY SHOEMAKER: The treatment of fibromata of the uterus by non-surgical methods is a subject of such importance that all data upon the subsequent behavior of such growths should be carefully recorded. Of peculiar importance is the question whether the sarcomatous or other forms of malignant degeneration are less liable to occur after treatment by the x-ray or radium, or whether they occur at all. While no exact percentage can be given, sarcomatous degeneration is a definite risk in untreated fibroma of the uterus. Certain writers have argued that after x-ray treatment no cases of malignancy have been observed. It is obvious, however, that not until the end of a patient's life can it be stated that malignant degeneration will not occur.

The patient whose history is recorded was known to me through conference with her physicians for many years. She finally developed sarcoma in a fibroid tumor about seven years after x-ray treatment was begun, and five years after it was stopped. The patient, who is now 56 years of age, underwent at my hands nineteen years ago an operation for laceration of the perineum in consultation with Dr. John H. Musser. She then had no tumor. She was not seen again until April, 1914, when she was referred for operation. I removed a large tumor, which proved to be a sarcomatous degeneration of a multiple fibroid of the uterus. A very smooth recovery followed abdominal hysterectomy. One year after the operation she reports herself entirely well. It is the complications of fibroid tumors which render them important. In the study of end-results time is necessary. That treatment is indicated which best eliminates the complications as well as the tumor and which preserves, if possible, sexual characteristics. This treatment in a large proportion of cases is surgical.

DR. JOHN A. MCGILN: We must acknowledge that fibroid tumors of the uterus can be cured by x-ray therapy and that the method has a very important place in the treatment of neoplasms. Whether the treatment can entirely replace surgery is problematical. Hysterectomy for fibroids has a definite mortality. In the hands of the trained gynecic surgeon I believe this mortality is not over 1½ to 2%. According to the statistics of Mayer the x-ray causes the entire disappearance of a tumor in comparatively few cases. While statistics may be quoted showing that cases treated by the x-ray have not shown late degenerative changes, Dr. Shoemaker has reported a case tonight in which such change occurred, and other cases are known, both published and unpublished. I believe that at the present time surgery is the best treatment for fibroid tumors of the uterus, unless the patient is in such a condition as absolutely to contraindicate its use.

DR. SHOEMAKER, closing: During one month this winter I successfully did hysterectomy for four

fibroids complicated with large cysts or large pelvic abscesses. This illustrates that the complications are often very formidable and that they are very common.

A SYMPOSIUM ON NATIONAL HYGIENE.

THE ORGANIZATION AND ACTIVITIES OF THE INTERNATIONAL HEALTH COMMISSION.

JOHN A. FERRELL, M.D., Assistant Director-General, International Health Commission: At the suggestion of the chairman of your committee on public health I shall attempt to outline the development of the International Health Commission. The commission was created in June, 1913, by the Rockefeller Foundation for "The promoting of public sanitation and the spread of the knowledge of scientific medicine." Its immediate task contemplates the extension of measures for the relief and control of uncinariasis or hookworm disease to those countries and peoples where conditions invite. Active measures are in progress in several territorial units in the Southern States, Central America, the West Indies, British Guiana, in South America, and Egypt; and other countries have signified a desire to have the coöperation of the International Health Commission. This commission was the natural outgrowth of the Rockefeller Sanitary Commission, organized by Mr. John D. Rockefeller in 1909, and granted a million dollars to be used during the ensuing five years toward the eradication of hookworm disease in the United States. This commission was composed of thirteen of the country's leading educators, physicians and business men. Mr. Wickliffe Rose was selected as administrative head of the work. The State Board of Health of each state was selected as the agency through which to undertake the work. Eleven states invited and received the coöperation of the commission. The educated public soon began to regard hookworm disease as a problem worthy of serious consideration. The disease was found to exist among from 10 to 90% of the people. By the close of 1914 the number of persons in the South microscopically examined was 1,273,350. The number treated and reported, 694,516. Of 12,305 persons in twelve communities, 75% were examined; 26% were found infected; and 94% of these were treated and probably cured. Twenty-nine per cent. of these were actually re-examined after a course of treatment and all found to be cured. In these communities there were 2257 homes. Fifty per cent. of them in the beginning had no kind of a privy and those present were seldom over sanitary. When the work closed 88% of the houses had privies, and 81% were of an improved type. This intensive work has been carried one step further in British Guiana by the International Health Commission, under Dr. H. H. Howard, director for the West Indies. There are two staffs at work, under the general supervision of the surgeon-general, a sanitary, and a medical staff. The sanitary staff, financed by the government, enters the area first. When this staff completes its work it moves to another area, leaving in the district sanitary inspectors, employed permanently by the government, to insure the maintenance of the improved sanitary conditions. The medical staff, financed by the International Health Commission, aims at the examination of every person in the working area, and the treatment until cured of every person found infected. Both staffs

have made admirable successes and there is promise of wider application. The Rockefeller Sanitary Commission accomplished all that was expected by its founder and paved the way for the International Health Commission. In considering this larger work, Mr. Rose in 1911 set to work to collect, from all countries of the world, the available information on the distribution and prevalence of hookworm disease; the extent to which it was a handicap to the health and working efficiency of the people, the agencies at work toward its control; the results secured; and the methods employed. The results of this study indicated that the disease prevails in a belt of territory encircling the earth for thirty degrees on either side of the equator, inhabited by more than a thousand million people; that "the infection in some nations rises to nearly 90% of the entire population"; that the disease has probably been an important factor in retarding the economic, social, intellectual, and moral progress of mankind; and that "little or nothing is being done toward its arrest or prevention." In August, 1913, Mr. Rose went to London on invitation, with a view of establishing work in the English dependencies. The English government pledged its active co-operation in the work, and appointed an advisory committee to coöperate with the commission in the colonies, and the British West Indies appeared to all the logical region for beginning work. Barbadoes, Trinidad, British Guiana, Grenada, St. Vincent, St. Lucia and Antigua were visited by Mr. Rose. In 1914 he gave special attention to Egypt, Ceylon, the Federated Malay States, and the Philippine Islands. Dr. J. H. White was secured for a year from the U. S. Public Health Service to establish the work in certain of the Latin-American countries. In the West Indies Dr. H. H. Howard is now directing the work. Dr. Victor G. Heiser of the U. S. Public Health Service is to give general supervision to activities started in Egypt, and immediate direction to the extension of the work to other countries of the East as conditions favor. The work of the present year will cost the commission approximately \$400,000, which amount is supplied by the Rockefeller Foundation. Mr. Rose, the director-general, is open to suggestions regarding other fields of activities to be entered by the commission. I think I shall violate no confidence in saying that he has been giving considerable thought to the training of workers in preventive medicine. He recognizes also the pressing need in many countries of facilities for the care of the sick. The attack on hookworm disease has led to the consideration of a similar attack on such diseases as yellow fever or malaria. Other fields may open offering more fruitful effort in accord with the paramount aim of the commission, which is to help the countries to help themselves in bringing into activity their own working agencies with their own resources.

THE RECENT HEALTH MOVEMENT IN THE UNITED STATES,
WITH SPECIAL REFERENCE TO INFANT WELFARE WORK.

BY DR. JOSEPH S. NEFF.

DISCUSSION.

DR. A. C. ABBOTT: It is startling to realize that in an area of 30 degrees north and south of the equator, and encircling the world there resides a population of about 100,000,000 people, approximately 90% of whom are suffering from parasitic

ailments that rob them of their efficiency. To bring the matter more nearly home, the survey made by the Rockefeller Foundation of eleven of our own Southern states, with a total population of more than 2,000,000 of people reveals a like condition. Many of these people are incapable of effective work and thousands of the children are unable to profit by the education offered them. It is fortunate that the disease is easily cured, and that in the majority of instances it leaves no structural defect. Restoration to efficiency of this large part of our population must be looked upon as of the greatest economic importance. I am delighted that Dr. Ferrell has given us a chance to hear of the work of the International Health Commission, and I believe I speak for the college when I say that everything that lies in our power to forward that work will be gladly done.

DR. S. LEWIS ZIEGLER, Director of Health and Charities: I am much interested in the problem of the hookworm disease in the South presented by Dr. Ferrell, and the baby welfare problem in the North, discussed by Dr. Neff. I think Dr. Abbott has struck the keynote of the subject in his reference to it as an economic proposition, and this is the argument we have to use in order to secure funds for such work. The only thing that will bring about progress in the public health is a united community. I think any one convinced of the rightfulness of a question in which human life and health are involved will grant that which is necessary. The question of child hygiene is very close to all of us, and no one has done more in that direction, probably, than Dr. Neff. The problem is so vital that we should make every endeavor to demonstrate that our sole purpose is to bring about the greatest good to the greatest number.

DR. J. CLAXTON GITTINGS: Emphasizing some points concerning the infant welfare movement I may say that ignorance, and not poverty, is the chief cause of infant mortality; the properly selected and properly trained nurse, acting under proper supervision, who serves as the educator, adviser and counsellor of the poor upon matters related to health, is the logical cure for infant mortality; a division of the department of health devoted to child hygiene and employing an adequate number of nurses would aid largely in the reduction of this mortality. The chief causes of infant mortality are over-crowding, poor housing, poor hygiene and improper food. Poor housing and over-crowding are economic matters. When parents know the evil effects of these conditions they will move. Poor hygiene can be corrected. Improper food for the baby means improper preparation, and that means ignorance on the part of the mother. A series of evenings would be required to demonstrate what the nurse can accomplish in the education of the ignorant and superstitious mother in the care of the baby. It is the city's duty to conserve the health of its embryo citizens. I fear there are a few physician who look upon an attempt to ameliorate the conditions in the slums as Utopian. When we see the men and women who are making these problems their life study, and when we see the actual results in the reduction of infant mortality, the greatest skeptic must admit that the movement is past the experimental stage, that it is not an idealistic dream, but a feasible method for saving infant life, which has an almost infinite range of possibilities, dependent upon the extent to which the municipality aids and encourages.

MR. JOHN A. VOGLESON, Chief of the Bureau of Health: As I followed Dr. Ferrell's paper two distinct lines of endeavor in public health occurred to me: (1) Research work, which is of high importance; and, (2) work which more directly concerns the daily operation of the health department, namely, the practical application of knowledge already possessed, which was so well expressed by Professor Fisher in his careful analysis and report in 1908 on *The Conservation of the National Vitality*, when he said that the problem of prolonging life could be met to a great extent by the application of the knowledge already possessed by well informed persons of the medical profession, to a reasonable degree in a reasonable way. That is what we are trying to do in the Health Department of Philadelphia. In 1892 over 30% of our total mortality occurred in children under two years of age. At that time the children under two years of age represented 3½% of our population. In 1910 we had the beginning of our work in child hygiene in the Health Department as an organized line of endeavor. At that time the mortality for the year among children under two years of age was 25% of the total mortality, but they represented about 4% of the whole population. Passing through a shorter period to 1914, the mortality among the same group of children dropped to 20% of the total mortality, and they still represent about 4% of the whole population. In tuberculosis and diseases of the respiratory tract we have the next highest mortality. In the Bureau of Health today we are receiving an increasing coöperation by all classes of people. This is notably true in connection with the milk supply of the city. Our Child Hygiene Division began in 1910 with a small and devoted band of nurses, and without exception, every district to which a city nurse has been assigned has shown a lessened infant and general mortality.

DR. SENECA EGBERT: The first decade of the last twenty-five years represented a period almost of inertia upon the part of the laity and of the medical profession concerning public health. The second decade showed an awakened interest, and the last five years have revealed a remarkable activity on the part of the public and the profession. No one can predicate the economic results of the work outlined by Dr. Ferrell. We may all take much pride in the fact that so much of this work is in the hands of men of the American medical profession. We have reason to be just as optimistic in the matter of the reduction of infant mortality. Credit is due to every department of the Health Bureau for improvement in public health. The medical inspection of schools is under the direction of Dr. Cornell. Many do not yet realize the value of the new water system in the health of the city and that for the money invested we have a return of over ten million dollars annually in the saving of life, and health and money capitalization to the city.

DR. RANDLE C. ROSENBERGER: Infantile mortality, due to whatever cause, is the most vital question in child welfare. Were it possible that pregnant women might be excluded from occupations injurious to health and rest given to the mother before birth, or the establishment, as in France and Germany, of a law protecting the mother against want during pregnancy and the puerperal state, by financial aid up to six weeks, nursing money to the twelfth week, and medical aid given, it would be a glorious undertaking. It is claimed that in France since the establishment of motherhood insurance in-

fantile mortality has decreased 50%. Education regarding the care of the child should be insisted upon. Girls should be given a course of instruction upon the care of children and in child hygiene fitting them to become teachers or mothers. The helpless child must be looked after by legislation and social endeavor. There should be coöperation of parents in the promotion of child hygiene. Recreation should be educational as well as a matter of amusement. Of the hygiene of the teeth too much cannot be said, and it must be remembered that facial deformity and nasal stenosis may be prevented, according to Bogue, by operations upon the temporary teeth of young children. It is claimed that 65% of feeble-mindedness is hereditary. Regarding the other 35% there seems to be a contrariety of opinion whether sterilization or segregation is the better means of treatment.

DR. FERRELL, closing: I count it a great privilege to be here this evening, and to hear the discussions that have been presented. We face everywhere the problem of funds adequately to conduct health work. We are endeavoring to determine what will constitute the smallest working unit. In the rural districts it may be a school district, perhaps a township. In the cities it may be only a block. If we can decide upon a plan of work effective for that small area, and determine the cost of the work for that unit we could have definite information to present to the people. After intensive work for a few months in the small area we could give to the people convincing information and show that to have the same benefits in larger measure it is only necessary to multiply such areas, and that for this funds would have to be forthcoming.

Book Reviews.

The Ductless Glandular Diseases. By WILHELM FALTA. Vienna. Translated and edited by MILTON K. MEYERS, M.D., Neurologist to the Lebanon Hospital, Philadelphia. With a Foreword by ARCHIBALD E. GARROD, M.D. (Oxon.) F.R.C.P., (Lond.) F.R.S. Physician to St. Bartholomew's Hospital, London. Philadelphia: P. Blakiston's Son and Company. 1915.

The work of Biedl in Germany, Naamé in France, and of Schäfer in England has already placed before the medical profession in accessible form a statement of our present knowledge on physiology of the endocrine glands and internal secretions. Schäfer's monograph on this subject was reviewed in the issue of the JOURNAL for June 3, 1915 (vol. clxxii, p. 830). Falta's elaborate work in German, dedicated to the great masters His. von Müller and von Noorden, presents similarly the pathology, clinical aspects

and therapeusis of the ductless glands. It is based chiefly on observations made at the first medical clinic in Vienna. The present excellent translation by Meyers makes this important work for the first time available to English speaking physicians who have not a reading acquaintance with German. The translator has also added at the conclusion of nearly every chapter a valuable editorial comment, based on his personal reading and experience, in which he aims to present the views of other investigators and clinicians when they differ from those of Falta, and to summarize and coördinate all the data upon each aspect of the subject. The translation is on the whole flexible and idiomatic. The foreword by Garrod sketches the history of the study of the ductless glands from the time of Addison, who may be regarded as its founder. It also emphasizes the contributions of Claude and Gougerot on the subject of pluriglandular sclerosis. The text is presented in fourteen chapters, dealing respectively with general considerations, diseases of the thyroid, cretinic degeneration, diseases of the parathyroids, thymus, hypophysis, epiphysis, suprarenals, status lymphaticus and hypoplasticus, diseases of the sex glands, pluriglandular diseases, vegetative disturbances, diseases of the insular apparatus of the pancreas and the different forms of obesity and adipositas dolorosa. The book is abundantly and admirably illustrated with 101 figures; and, besides the references given at the close of each chapter, has an elaborate classified alphabetic bibliography of over fifteen hundred titles arranged in fourteen chapters. This volume, which should prove of the greatest interest and value to practitioners and students, is a monument of scholarship and clinical research.

The Individual Delinquent. A Text-book of Diagnosis and Prognosis for all Concerned in Understanding Offenders. By WILLIAM HEALY, M.D., A.B., Director of the Psychopathic Institute, Juvenile Court, Chicago. pp. xvi—830. Boston: Little, Brown and Company. 1915.

Many books have been written upon delinquency and the delinquent, but this, so far as we are aware, is the first that has given special emphasis to the individuality of the offender. Herein lies the chief merit of this really monumental piece of work, that delinquency is studied, not as a single type of moral or physical disorder, but rather as a condition which varies with each individual. Dr. Healy has applied to his study the case system, of which much has been heard since its original introduction at the Harvard Law School and later at the Harvard Medical School. By this method one gets forth-

with at actual facts in individual lives; this plan has been adopted by Healy with the result that he has produced a book of extreme practical value, embodying facts and not mere theories.

As a pioneer worker and in fact organizer of the juvenile psychopathic institute in Chicago, Dr. Healy has had a peculiar opportunity to apply his principles of research in a vastly important and much neglected field. He has proceeded in a purely objective way and his deductions are tentative, in view of the relatively few intensively studied cases. The subject matter of the book is divided into twenty-seven chapters under two general headings: (I) General Data, and (II) Cases, Types, Causative Factors. In the first section, which he calls Book I, after an introduction presenting the general plan of the research and certain general principles with which broad minded persons must be in substantial agreement, chapters are devoted to Orientations, the Individual, the Mental Bases of Delinquency, three chapters on Working Methods, one on Statistics and two on General Treatment. In this portion of the volume methods, which have multiplied to a somewhat alarming extent of late years, are given in considerable detail, with estimates of the value of various tests. The method of case taking is described in detail and naturally forms an important part of the book from an educational standpoint, since upon a carefully taken history and its proper interpretation must depend the ultimate determination of the case. It is gratifying to those who believe that the psycho-analytic method has been a step in advance, rather than a retrograde movement, to find a very fair statement of the present and possible future value of this means of psychological research. In general, this section of the book will be read with eagerness by students of the subject and teachers, but with a certain regret that it could not have been somewhat more condensed.

The second part of the volume (Book II), comprising about 600 pages, is concerned with the histories of characteristic cases. This portion of the book is altogether excellent and must be read to be fully appreciated. As suggested above, it affords an application of the case method worthy of imitation by all who are desirous of studying social problems by other than the usual rule of thumb method. A valuable appendix to the book is an extensive bibliography on the general subject of delinquency.

Originality is sufficiently unusual in any walk of life, and particularly in the making of books. Dr. Healy, however, has achieved a distinctly new departure in presenting an old and much discussed subject from a wholly new and suggestive point of view. That this book will be a pioneer and the forerunner of others with similar intent, is not to be doubted. The author makes no claim to finality, and simply blazes the trail for others to follow. It is certainly one of the most significant books of the last decade.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Saturday, from one to two-thirty p.m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

SIR JAMES McGRIGOR, BART.,
M.D., K.C.B., F.R.S.

Of the eminent surgeons who have served at the head of the British Army Medical Corps few have been more distinguished or have had the fortune to have their activities fall in a more brilliant or critical historic epoch than the Scotsman Sir James McGrigor, who was to Wellington what Larrey was to Napoleon in the great wars of a century ago. Centering as his long career did, about the battle of Waterloo, McGrigor's life is particularly recalled by the recent centennial of that momentous event and has been sketched at length in the *British Medical Journal* of July 25, 1914 and June 12, 1915.

James McGrigor was a highlander, born at Leithendrey in Strathspey, Invernesshire, in 1771, the son of a merchant. He was educated at the grammar school in Aberdeen and at Marischal College, from which he received the degree of M.A. Not wishing to follow his father's occupation he was attracted to the study of medicine,

partly through some of his companions, partly through visits to the Royal Infirmary. He studied medicine for three years at Aberdeen and subsequently at Edinburgh and Glasgow, though he did not at that time obtain his degree. In 1793 he became a surgeon in the 88th regiment of Connaught Rangers which, in 1794, was sent to Jersey, an island then occupied by French exiles. In the unhygienic conditions to which they were subjected typhus broke out among the members of his regiment and McGrigor himself survived the disease. Later his regiment was ordered to Flanders, where he took part in the sieges of Bergen-op-Zoon and Nimeguen. Here again typhus was extensively prevalent in the army, and McGrigor acquired such a valuable clinical experience with this disease that later, when it broke out in the concentration camps at Norwich, McGrigor was detailed to eradicate it, an accomplishment which he actually achieved largely by means of fresh air and cleanliness.

McGrigor was next sent with his regiment to the West Indies aboard the frigate *Betsy*, and on arriving at Granada found himself in the midst of an epidemic of dysentery and yellow fever. McGrigor survived both these infections and directed the activities of the medical staff during the subjugation of that island. In 1796 he returned to England, but in 1798 was ordered with his regiment to Bombay and thence to Ceylon. Here he became chief of the medical staff of Bombay and formed the acquaintance of Colonel Wellesley, with whom his associations thenceforth became most intimate and confidential. In 1801 he went as surgeon with an expedition commanded by Sir David Baird to Corsea and, crossing the desert, went down the Nile to Rosetta. On the voyage to Egypt many of the troops aboard were infected with the Guinea worm, and of his experience with this parasite McGrigor subsequently wrote as follows in his autobiography:—

"The disease is a very extraordinary one, and was new to me when I first met with it, although I was very well stocked with books, having had, I have reason to believe, a larger stock than most surgeons when we went to India. I looked in vain for an account of this loathsome and painful disease; I found mention merely of its name and antiquity, and that the only treatment was to pull it out daily."

At Rosetta, McGrigor assumed the medical superintendence of the army from India. While he was stationed with headquarters at Alexan-

dria the plague broke out in that city but was quickly subdued by McGrigor's efficient activities. On his return to Bombay he was appointed superintendent of local quarantine.

In 1804 McGrigor returned with his regiment to England and there left it after eleven years' service. He now received the degree of M.B. from Marischal College, but instead of settling in private practice immediately became surgeon of the Horse Guards Blue, then stationed at Canterbury. In this position he soon had to face an epidemic of hospital gangrene, which he controlled by removing his patients to new and scrupulously clean quarters. Later, at Windsor, McGrigor came under the favorable notice of George III and, happening at this time to have whooping cough, he had the honor to be cared for by the Queen herself. In 1805 he was gazetted deputy inspector, a position which, from its statistical functions, greatly appealed to his methodical Scottish temperament. In this office he instituted important reforms in the recording and preservation of army medical statistics. He writes as follows in his autobiography of the differences between the methods of his predecessors and the new system which he sought to introduce. He was perhaps one of the first to recognize the immense scientific possibilities and value of the medical statistics derivable from a large body of men under disciplinary control and supervision as in an army.

"The most minute and scrupulous attention was not only exacted in the number of ounces of soap, salt, oatmeal, etc., given to each patient, but an error even in the fractional parts brought down the animadversion of the board, and was frequently the subject of protracted correspondence; while no notice was taken of any new or extraordinary feature of prevailing diseases, no proposition for the trial of new remedies and for the return of reports thereon, nor any injunctions issued to notice post-mortem appearances. In short, nothing with regard to professional duty in the interests of science was noticed, unless there happened to be an extraordinary mortality in a corps. About this time, and for some time afterwards, the duties of regimental surgeon and assistant-surgeon were chiefly those of clerks, as accountants to the public for their expenditure on each sick man."

McGrigor was assigned to the northern district with headquarters at Beverly, and there undertook an extensive reform, not only of statistics but of the administration of military hospitals. He writes with a tone of genuine modern enlightenment on the importance and

function of such hospitals in the organization of an efficient army:—

"It is not only in the sense of humanity, but in that of a sound policy and real economy, that the state should provide able medical and surgical advice for the soldier when sick or wounded: I look upon it to be an implied part of the compact of citizens with the state, that, whoever enters the service of his country as a soldier to fight its battles, should be provided with the same quality of medical aid, when sick or wounded, which he enjoyed as a citizen. In every large town, whence the great bulk of recruits is drawn, there are public hospitals and dispensaries which, supported by the subscriptions of the rich, are always open to the sick and poor, and to persons of the middle classes; in fact, to those ranks in life from which the soldier comes. The physicians and surgeons of these public institutions are always the ablest men in the profession of medicine. After the enjoyment of such medical aid, the soldier should not, therefore, be consigned to the ignorant and uneducated of the profession; he is clearly entitled to the same quality of medical advice as when he was a citizen, and is not to be put off with a cheap article of a doctor, and with one who could not afford the expense of a regular medical education."

Later McGrigor was transferred to the southwest district, with headquarters at Portsmouth, where he received and dealt with the large numbers of sick and wounded after the battle of Corunna. Typhus again broke out among these troops, but was quickly suppressed by McGrigor through the use of floating hospitals which relieved the congestion of the wards on land.

In 1811 Dr. McGrigor was ordered to Walcheren to succeed Sir John Webb as chief of the medical department there. He was, however, shipwrecked on his way to Flushing, and, returning to England, was sent, in 1812, to Lisbon, to act as chief of the medical staff under Lord Wellington. It was in this Peninsular War that McGrigor now first gained national distinction, as an efficient medical administrator under circumstances of trying difficulty. His professional and administrative genius were particularly tried after the battle of Salamanca and the siege of Badajoz. Indeed, McGrigor was present in every battle in that war, including the last engagement at Toulouse. Napier in his "Peninsular War" bears striking testimony to the efficiency of McGrigor's medical administration.

"During the ten months from the siege of Burgos to the battle of Vittoria the total number of sick and wounded which passed through the hospitals was 95,348. By the unremitting attention of Sir James McGrigor and the med-

ical staff under his orders, the army took the field preparatory to the battle with a sick list under five thousand. For twenty successive days it marched towards the enemy, and, in less than one month after it had defeated him, mustered, within thirty men, as strong as before; and this, too, without reinforcements from England, the ranks having been recruited by convalescents."

Upon their return to London at the close of the war the friendship between McGrigor and Wellington continued, and as a result of the latter's influence as well as of his own distinguished services McGrigor was knighted and retired on an allowance of £3 a day. The brief period of leisure thus afforded to him McGrigor devoted to attending lectures on anatomy and chemistry.

The return of Napoleon from Elba, however, soon called England again into the field, and McGrigor was summoned from retirement, and on June 13, 1815, appointed director-general of the medical department with the relative rank of major-general. He was present at the battle of Waterloo and directed the medical relief of the allied armies thereafter. Even with the defeat of Napoleon, McGrigor was not permitted again to pass into retirement; for so active and salutary were the reforms and improvements which he instituted in the army medical service that he was retained in his position until 1851. He was held in the highest esteem, not only by Lord Wellington, but by the government, the King, his colleagues, subordinates and patients. In 1831 he was created a baronet and in 1850 was made a K.C.B. He was a Fellow of the Royal Society of London and was thrice elected rector of Marischal College, Aberdeen. During these years he continued his valuable services to the British Army Medical Corps.

"Allusion has already been made to his investigation into the professional equipment of all the medical officers in the army; but no less important was his statistical research into the health and condition of the troops at all the home and colonial stations, the diseases prevalent, and the modes of treatment pursued. Through the reports and returns which he thus received half-yearly from all over the world he collected a mass of materials of the greatest value, bearing upon the health of the army. He found out the average duration of the life of the soldier in different climates, the causes of their diseases, the mortality in various years from cholera, yellow fever, and other maladies, and the effects of new sanitary methods both of prevention and of cure. His name will also ever be honorably associated with the Army Medical

Friendly Society for the relief of widows of army medical officers, which he started in 1816, and with the Army Medical Benevolent Society for the benefit of the orphans of medical officers, which he established four years later. He formed, too, at Chatham a Museum of Anatomy and Natural History bearing upon military surgery and the library attached thereto, to which he contributed no fewer than 1500 volumes."

McGrigor himself was not a voluminous writer, but his medical sketches, memoirs, letters and autobiography are models of concise, yet picturesque, vigor and accuracy in style.

For fifty-seven years Sir James McGrigor devoted his energy and genius to the medical service of his country, a service during which he had had not only the hardships of his profession, but had passed as many battles, dangers and shipwrecks as Othello; yet after this "life of sturt and strife" he survived to enjoy six years of peaceful retirement in London, where he finally died on April 2, 1858 "without pain and almost without disease." In his personality he combined the best qualities of the doctor and the soldier.

"In addition to his great ability as an administrator, McGrigor had the qualities of character that command success. Ever straightforward in his dealings, he combined tact and courtesy with firmness in a most unusual degree. From the time of his joining the Connaught Rangers to the very end of his career he was recognized as an officer who could be trusted to do his duty at whatever cost to himself. The confidence of the soldiers in him reminds one of the story of Ambroise Paré's reception by the garrison of Metz, 'Our Ambroise is with us; we shall not die.' From first to last he was on the best of terms with the officers of his own department, and also with those of the combatant branches. It must never be forgotten that he placed foremost in his desires the health of the soldier; that he worked hard to raise the professional and educational status of the army medical officer; and that he showed a true devotion to the scientific aspects of medicine which was admirable in a life so full of departmental worries and absorbing preoccupations."

EXACT METHODS IN PSYCHIATRY.

A difficulty in the phychiatric field has been the failure of exact methods of determining the significance of mental states. The coldness which has been manifested toward this branch of medicine by practitioners of scientific bent has been due largely to the fact of the general indefiniteness of the subject. Laboratory methods have

been difficult of application and hence in the present phase of medical opinion the whole subject has been regarded as rather outside the pale of orthodox scientific investigation. It is, however, evident that a change is coming in this attitude and that methods, psychological and of othersorts, are being applied with hope of definite and exact results. All that has grown out of the Binet methods for example, is a step in this direction, not to speak of the more disputed analytical methods of investigating mental phenomena which still are on trial. A still further step toward the desired end of exactitude is illustrated by the work which Dr. G. Philip Grabfield has been doing for the past year at the Boston Psychopathic Hospital in connection with the sensory threshold for faradic stimulation in psychopathic subjects. A further communication on this general subject is printed in this issue of the JOURNAL. Although the number of cases as yet studied is too few upon which to base a broad generalization, it can hardly be doubted that considerable significance is to be attached to this graphic method of determining emotional states. Grabfield in general finds that in the psychosis now known as manic-depressive insanity, during the manic phase a normal threshold for faradic stimulation is maintained, whereas in the depressed stage there is almost invariably a pathologically high threshold. If it be finally proved that a high threshold or diminished sensitivity is characteristic of depression as observed in that psychosis, it becomes evident that a somewhat valuable means of diagnosis of an exact nature is at hand. This possibility Grabfield believes to be a fact. He states in one place, "that the differentiation of true depressions of this psychosis (manic depressive) from those of the psychoneurotic group will be made vastly easier by the determination of this threshold is definitely indicated by the evidence which is at present available." Whatever the ultimate significance of this work on faradic stimulation may prove to be, it is certainly a step in the direction of applying scientific methods to the abstruse problems of the mind and as such constitutes a further bond of association between the field of so-called internal medicine and of its closely related subject, psychiatry. If psychiatry is to come into its own, it apparently must ultimately embrace in its field all the branches of medicine from which it now too often appears to be sharply separated. Work such as this of Dr. Grabfield tends to bring this day nearer.

SPECTACLED SOLDIERS.

A question which is now engaging the attention of recruiting officers across the sea is the advisability of allowing men who wear glasses to enlist in the army. Should the United States become involved in this or any other war this problem would be presented to our army and more particularly to the army medical officers. It might indeed assume grave proportions with us on account of the prevalence of visual defects among Americans.

An argument against enlisting such men, which will at once occur to military surgeons and to other physicians who have attended men in prisons or other places where there was a temptation to avoid duties of various kinds, is the ease with which men with glasses may avoid active duty, if they are so inclined, by simply breaking or losing their glasses. Then of course these accidents may actually happen and deprive the army of the recruit's services for a period if the visual defect be of such a degree as to incapacitate him.

Another factor which must be taken into consideration is the severe character of wounds of the orbit in soldiers wearing glasses. This peculiar susceptibility of spectacled men is recognized by the laws of most communities which provide for a harsher penalty for one committing an assault on a man with glasses than on one without. It is also considered hazardous for such a man to play professional baseball, so much so that we find in the two major leagues, employing between three and four hundred players, only one man with glasses and he is regarded as something of a curiosity, being the only one of the sort for a number of years. A projectile striking a pair of spectacles with considerable force would drive the splintered fragments of glass directly into the brain, inflicting an almost necessarily fatal wound. This is not pure hypothesis, for since the present war began we have received frequent reports of severe injuries sustained by officers wearing wrist watches which came into contact with flying pieces of shell or bullets. Even those in the immediate vicinity of soldiers wearing glasses might be endangered by the fragments of glass, just as is the case now with wrist watches.

Of course there will be some applicants for enlistment who will be desirable on account of special knowledge or because they have had experience which fits them for certain depart-

ments of the army, even though they are handicapped by some visual defect. Then, too, the exigencies of the situation may become such that disabilities of this kind will have to be waived.

The whole matter will, of course, be decided by the military authorities, but it seems that the opinion of the medical profession, which will undoubtedly be asked, will be against the enlistment of men with glasses on account of the ease with which they may malingering, their liability to become incapacitated by accident to their glasses and the peculiarly severe nature of the wounds which they may sustain.

A YEAR OF THE EUROPEAN WAR.

THE first year of the great European War has come to an end. Already this war has lasted considerably longer than was generally prognosticated at its outbreak; and the prospect of its early termination seems perhaps more remote now than at any time since the beginning of hostilities. From time to time fresh nations have joined the belligerent powers, and it is not certain that still others may not become involved. A year ago today the assault upon Liège was in progress, and on August 7 that city was occupied by the hostile forces. The events which have succeeded during the ensuing year have marked an unprecedented epoch in the world's history, and have been characterized by an intensity of dramatic interest which has appealed to every class and to all races. Biologically, politically and sociologically, as well as in its medical and human aspects, the European War remains for physicians, as for men of every other walk in life, the great outstanding phenomenon of the twentieth century.

During the past year the JOURNAL has endeavored to present to its readers chiefly such aspects of the great conflict as have a professional and scientific interest. Through its special correspondents it has fortunately been able from time to time to record at first hand the experiences of physicians, not only in the various belligerent countries, but in hospitals, ambulance corps, and at the several arenas of the war. It has already been able to publish several original articles based on the actual experience of war surgery and expects to be able to publish more, as time proceeds. The JOURNAL will soon have the especial privilege of printing a valuable series of extracts from personal letters of Dr.

Richard P. Strong, dealing with his experience in the suppression of the typhus fever epidemic in Serbia, one of the most noteworthy achievements to the credit of the American medical profession during the war.

As the European War continues, its interest and importance increase rather than diminish; for not only are its events of a stupendous and colossal magnitude, but its settlement is fraught with momentous consequences which will profoundly affect the future aspect of civilization throughout the world. As a scientific periodical, the JOURNAL has remained and will continue dispassionately neutral in its view of the phenomena of the war, and until the conclusion of the conflict will endeavor to present in due proportion in its columns those events which have a particularly medical bearing. In the present issue, grouped for the first time under a special heading, are several topics of particular concern: the withdrawal of American Red Cross aid, the establishment of an American relief hospital at Florence, the award of a decoration for heroism to an American physician. To the physician, perhaps more than to men of any other profession, nothing human is alien; and not only does our profession play a large and critical part in the actual events of war, but it is likely to have an even more prominent rôle in the racial reconstruction which must follow.

MEDICAL NOTES.

NEW YORK BABIES DO WELL DESPITE THE HEAT.—According to figures compiled by Registrar W. H. Guilfoyle, of the Department of Health, there were 1299 deaths reported during the past week, with a rate of 11.67 per thousand of the population, as compared with 1331 deaths and a rate of 12.44 during the corresponding week of 1914, a decrease in the absolute number of deaths of 32, and a decrease in the rate of 0.77 of a point, which is equivalent to a relative decrease of 86 deaths.

The mortality from diarrheal diseases under five years of age, notwithstanding the extremely hot weather of the week ending July 17, 1914 (diarrheal death rate ordinarily increases after the third day of extremely hot weather), showed the decreased mortality of approximately 8%.

The number of deaths from heat stroke was nine, one more than the number in 1914.

Tuberculosis and accidental deaths were the only other causes that showed an increased mortality.

The mortality from typhoid fever was 60% lower than in 1914.

The Borough of the Bronx showed the extremely low rate of 7.83 per 1000 from all causes.

The death-rate from the first of January, up to and including Saturday, July 24, was 13.86 per 1000 of the population, as compared with a rate of 14.37 during the corresponding period of 1914.

BOOK AGENT CLAIMS TO BE HEALTH DEPARTMENT NURSE.—Commissioner Goldwater lately sent out a warning to New Yorkers to be on the lookout for a wily woman book agent who secures her introduction into homes where there is a case of contagious disease by representing herself to be from the Department of Health. In an instance reported in Brooklyn, the mother of a child ill with measles was visited by a woman who said she came from the Board of Health and had received word of the case and that she had called to tell how to treat such cases. Under the belief that this woman was from the Health Department and that the publication she represented was sanctioned by it, the mother was induced to sign her name to a blank and pay one dollar down. After a while, she began to realize that she was buying a book on health and longevity, which was to be paid for twenty-five cents a week for many months, and thereupon demanded her money back, which was refused, the woman departing saying that the book would be sent the following Monday. The receipt she left tells of a book on health through which people are taught how to get along without doctors, by treating their own families according to the prescriptions therein. The book is to cost twelve dollars, and there is no address on the blank.

Almost needless to say, the Department of Health is not promoting the sale of any particular book on health. On the contrary, it is glad to send, free of charge to all who ask, carefully written circulars of information regarding almost all matters of public health, including, of course, special leaflets on the various contagious diseases.

HONAN BIOLOGICAL INSTITUTE.—It is announced in a recent issue of the *British Medical Journal* that the new building of the Honan Biological Institute at Queens College, Cork, Ireland, has recently been completed with funds provided by the trustees of the estate of the donor.

"In the new building ample room has been provided for the study of zoölogy, botany and geology. There are junior and senior zoölogical and botanical laboratories, as well as research rooms, geological and geographical laboratories, and a large semicircular lecture theater, lighted from the roof, and capable of accommodating about 100 students."

UNIVERSITY OF CINCINNATI MEDICAL COLLEGE.—It is announced in a recent issue of *Science* that during the past month the Medical College of the University of Cincinnati has received several large gifts.

"Mrs. Mary M. Emery promised the university the sum of \$250,000 for a new Medical College building, on the condition that an additional \$250,000 be raised by July 1 for its equipment and maintenance. At the appointed time, Dean C. R. Holmes, of the College of Medicine, announced that \$250,000 had been secured. The new structure will be located on grounds adjacent to those of the Cincinnati General Hospital, which occupies 24 buildings and covers 27 acres, and which offers unusual opportunities for clinical instruction. The sum of \$30,000 has just been raised by citizens of Cincinnati for the purpose of maintaining for three years a chair of medicine in the Medical College. The chair will be known as the Frederick Forchheimer chair of medicine, in honor of the late Dr. Frederick Forchheimer, who was for years professor of medicine at the Medical College. Dr. Robert S. Morris lately of Clifton Springs, New York, and formerly of Ann Arbor and of Johns Hopkins University, has been appointed to the new position."

THE DEVELOPMENT OF TROPICAL COUNTRIES.—In an address delivered in Cincinnati, General William C. Gorgas made the following pertinent remarks regarding the effect of improved sanitation in tropical countries on their industrial development:—

"The real scope of tropical sanitation which has been almost entirely developed within the last fifteen or twenty years, I believe, will extend far beyond our work at Panama. Everywhere in the tropics, to which the United States has gone in the past fifteen years, it has been shown that the white man can live and exist in good health. This has occurred in the Philippines, in Cuba and in Panama, but the demonstration has been most prominent and spectacular at Panama, and therefore has attracted there the greatest world-wide attention. Here among our large force of laborers we had for ten years some ten thousand Americans, men, women and children. Most of these American men did hard manual labor, exposed to the sun, rain and weather conditions day in and day out, yet during that time their health remained perfectly good, just as good as if they were working at home. The same remark as to health would apply to the four thousand women and children who lived at Panama with their husbands and fathers. Both the women and children remained in as good condition as they would have been had they lived in the United States. This condition at Panama, I think, will be generally received as a demonstration that the white man can live and thrive in the tropics. The amount of wealth which can be produced in the tropics for a given amount of labor

is so much larger than that which can be produced in the temperate zone by the same amount of labor that the attraction for the white man to emigrate to the tropics will be very great, when it is appreciated that he can be made safe as to his health conditions at a small expense. When the great valleys of the Amazon and of the Congo are occupied by a white population more food will be produced in these regions than is now produced in all the rest of the inhabited world."

EUROPEAN WAR NOTES.

TYPHUS IN SERBIA UNDER CONTROL.—On July 22 it was reported by the American Vice Consul at Belgrade that the epidemic of typhus fever at Serbia and Montenegro is now under complete control. It is added that the cost of continuing the control of pestilential diseases in Serbia during the next two months is estimated at \$10,000.

WITHDRAWAL OF RED CROSS FROM EUROPE.—Report from Washington, D. C., on July 25 announces that on October 1 the American Red Cross will withdraw 14 of its units from the various belligerent countries, leaving only the two units in Belgium, where it is believed that the need for them is greatest. This withdrawal is made necessary by lack of sufficient funds to maintain the units at their present stations. The Serbian sanitary commission, however, whose support has been provided for by special contribution, will continue its work. A statement has recently been issued by Miss Mabel T. Boardman, chairman of the American Red Cross Relief Committee, showing the exact amount and kind of relief sent to the various countries:—

"The Red Cross sent to the warring countries 367 persons engaged in humanitarian enterprises. Of that number 71 were surgeons and 253 nurses, while 43 were members of the Serbian sanitary commission. England, France, Russia, Germany, Austro-Hungary, Serbia and Belgium each received one or more units, which means one or more complete hospitals, with doctors, nurses and other attendants, and with all necessary supplies and equipment. The administrative expenses of the huge undertaking have already amounted to \$11,291, and this has been paid by the Red Cross itself and not taken from the fund contributed for relief.

"The report shows that the Red Cross has sent into the war zone almost 1,000,000 pounds of cotton for the hospitals, 882,000 yards of surgical gauze, 65,000 yards of crinoline, 727,000 assorted bandages, 33,000 yards of adhesive plaster, 9240 stretchers, 10,267 blankets, and other supplies in proportion and 19 motor ambulances for the Red Cross personnel. There were also four army field hospital outfits, 50 army hospital tents and 30 field medical tents.

"Following is a summary of services rendered each belligerent government:—

"Austria, 11 shipments, value \$97,683; Belgium, 12 shipments, \$96,708; England, 13 shipments, \$87,843; France, 24 shipments, \$216,155; Germany, eight shipments, value \$182,795; Italy, two shipments, \$14,451; Montenegro, three shipments, \$15,326; Poland, one shipment, \$7200; Russia, nine shipments, \$89,613; Serbia, eight shipments, \$130,867; Turkey, two shipments, \$12,536.

"The financial statement shows expenditures of \$1,450,306, leaving a balance of \$174,818 on hand, for which the demands already are heavy."

ORGANIZATION OF AMERICAN COMMITTEE FOR RELIEF WORK FOR ITALIAN WOUNDED.—The following announcement has been made relative to the organization of an American committee for war relief in Florence:—

"Upon the intervention of Italy in the European War, a meeting of Americans resident in Florence was convened to institute and organize relief work for the Italian wounded. At this meeting it was unanimously resolved to equip and maintain a hospital for convalescent private soldiers discharged from the military hospitals, but not yet able either to rejoin the colors or to return to their homes. To this end a general committee was appointed, with the title American Committee for War Relief in Florence.

"Upon application to the authorities of the Italian Red Cross the committee was most courteously offered the use of the commodious and historic Villa del Sole di Camerata, previously placed at the disposal of the Red Cross by its owner, Cav. Dott. E. Modigliani. With ample capacity for one hundred hospital beds, surrounded by a spacious park and garden, and furnished with modern appliances for heating, lighting and sanitation, the Villa Modigliani is admirably adapted for our purpose. Properly equipped and maintained as a hospital, it will be an offering to the Italian people, in the hour of stress, worthy of the sincere and grateful friendship borne them by Americans who have loved their country and its past, and look with confidence toward its future. All expenses of equipment and maintenance will be met and financed by the American committee.

"The medical staff will be appointed by the Italian Red Cross, with the coöperation of the American committee, which will further charge itself with such functions as may be delegated to it by the medical authority.

"The resources of the American colony in Florence are insufficient for the maintenance of the hospital upon a scale commensurate with the opportunity and the need. Its members hope, therefore, to enlist the interest and financial coöperation of their fellow-countrymen who have known something of the beauty and inspiration of a city which has contributed so generously to the ideal life of our civilization.

"The initial expense of equipment for one hundred beds is estimated at four thousand dol-

lars; the monthly expense of maintenance at the same sum. The cost of this hospital for one year, upon this basis, will, therefore, be not less than fifty thousand dollars. Toward this sum more than twenty thousand dollars have been pledged, by Americans resident in Florence, chiefly in monthly subscriptions.

"The committee looks confidently to the larger American public for their sympathy and coöperation. It is hoped that a sum will be subscribed sufficient to enable the hospital to receive and care for as many patients as the space at our disposal may warrant.

"Checks should be drawn and sent with the detachable form, duly filled in, to H. Blakiston Wilkins, Treasurer, 4 Via Bernardo Rucellai, Florence. American checks may be sent to H. Blakiston Wilkins, treasurer, care of Bankers Trust Company, Wall Street, New York."

SECOND HARVARD SURGICAL UNIT.—Report from Europe on July 28 states that the second Harvard Surgical Unit, which sailed from New York City on June 26, is now at service in charge of a British base hospital of 1000 beds in France, the exact location being deleted by the censor. The unit is under official chief command of Lieutenant-Colonel Sir Allan Perry, R.N.M.C. Dr. E. H. Nichols, the surgeon-in-chief of the unit will return to the United States about September 1. On Saturday, July 31, there sailed from New York aboard the steamship *Philadelphia* for England, whence they will proceed to France, Dr. Edward P. Richardson, Dr. Channing C. Simmons and Dr. Donald B. Sternburg of the Massachusetts General Hospital. It is expected that this party will arrive in France about August 10.

TYPHUS FEVER IN EUROPE.—The weekly report of the United States Public Health Service for July 23, 1915, notes that during the fortnight ended June 5, twenty-three cases of typhus fever in the military service were reported in Germany. During the same period the disease was reported present among prisoners of war in Baden, Saxe-Coburg-Gotha and in seventeen German government districts. During the week ended June 10, twenty-three cases and seven deaths of the disease were reported in Alexandria, Egypt. During the fortnight ended May 8, 645 cases were reported in Austria, chiefly among soldiers of war and persons from Galicia.

FRENCH GOVERNMENT HONORS CAMBRIDGE PHYSICIAN.—It is announced that Dr. Richard Norton, of Cambridge, Mass., has been awarded the decoration of the "*croix de guerre*" by the French government for great gallantry in rescuing a number of wounded during the evacuation of a village within 600 yards of the hostile lines and under heavy fire, in which he "*avec un sangfroid et un phlegme de merveilleux a eu ses*

voitures percés de projectiles." Dr. Norton has been serving since August, 1914, in command of a British corps of 80 motor ambulances in Flanders.

WAR RELIEF FUNDS.—On Aug. 1 the totals of the three principal New England relief funds for the European War reached the following amounts:—

Belgian Fund	\$266,442.37
Red Cross Fund	137,647.75
Serbian Fund	35,845.55

BOSTON AND NEW ENGLAND.

GIFT TO HARVARD FOR MEDICAL RESEARCH.—It is announced that Mr. Douglas Flattery of Boston has presented to the president and fellows of Harvard College a fund of which the annual income will be about \$800 for the encouragement of scientific study of the cause, cure and prevention of disease. The terms in which this gift is made are as follows:

"I am prompted to this gift by the belief that much knowledge of those diseases of which the cause and treatment are at present wholly or in part unknown will be acquired in the future through the persistent study of those diseases by skilful and industrious workers, who may be able to devote their whole time for a given period to such study. It is my hope that the income of this fund will enable and encourage both young men of marked promise and investigators of brilliant achievement to pursue those scientific studies in the fields of medical or surgical research for which they are highly qualified, or show special adaptability.

"The income is annually to be assigned by vote of the president and fellows of Harvard College, unless in their wisdom and unrestricted authority the purpose of this gift could best be served by withholding the income for any year or any term of years, but I would prefer an annual appointment, for not more than three years.

"In expressing my hope for the disposition of the income of this fund, I do not wish to impose any restrictions upon the authority of the president and fellows of Harvard College other than that the income be for all time devoted to the promotion of the scientific study of the cause, the cure and the prevention of disease.

"If, in your judgment, the amount is insufficient to get the results desired I am willing to consider the advisability of increasing the capital now or in the future."

NEW PLYMOUTH HOSPITAL.—The new building of the Plymouth (Mass.) Hospital was dedicated on Thursday of last week, July 22. The money for this building and a sum for its endowment were given by Mrs. Rosa Cole of Kingston, Mass. The cost of the building was \$100,000. There is a general surgical and a medical ward, an isolation ward, boiler room and laundry. The old

building is now used for administration and the two are connected by a passageway. The new building is equipped with silent electric signals, electric elevators and a German system of indirect lighting.

MASSACHUSETTS DEPARTMENT OF HYGIENE.—In the issue of the *JOURNAL* for June 3d we noted the appointment of Professor Selskar M. Gunn as chief of the newly-established division of hygiene of the Massachusetts Department of Health. This division has recently issued a statement regarding measles, for distribution over the state, calling attention to its dangers, prevalence and the necessity of careful nursing during the course of the disease. Professor Gunn states that about five hundred babies die each year in this state from measles, and a large number of other deaths, charged to bronchial pneumonia, are primarily due to measles. In January there were 1118 cases. The number steadily increased until the returns for the month of May showed 4809 cases. Practically all the fatal cases of measles in this state are children under six years of age. The division has in preparation the publication of a book on the baby for mothers and a traveling exhibit on child welfare. Films showing educational pictures about such topics as the milk supply and typhoid fever will be furnished various moving picture theatres. Educative work in co-operation with the American Society for the Control of Cancer is also being prepared.

CARE OF HOSPITAL RECORDS.—The Massachusetts General Hospital has published in the form of a pamphlet a complete statement of its system of caring for hospital records. It describes minutely the exact routine followed.—the admission of a patient, the writing of the record, directions for work on records, duties of the custodian, daily inspection of charts, weekly inspection of records, name and result catalogue, follow-up work, the clinical catalogue and the ultimate binding of the record. For the purpose of standardizing the methods of keeping hospital records this statement will be valuable.

COST OF THE EPIZOOTIC OF FOOT AND MOUTH DISEASE.—It is announced by the Massachusetts Bureau of Animal Industry that no case of foot and mouth disease has been reported in this state since April 17. Forty-nine cities and towns and ninety-seven farms were involved in the epizootic of this disease last winter as a result of which there were slaughtered 6116 infected swine, 2114 cattle, 1697 fowl, 77 sheep and 11 goats. The value of these animals was appraised at \$230,994.38 for which the owners are reimbursed by the state and nation, each of which meets one-half of the expense. The total cost met by the Commonwealth of Massachusetts, therefore, amounts to \$115,472.19. The majority of these payments have already been made.

MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH.—A quarterly meeting of the Massachusetts Association of Boards of Health was held at the Pemberton Inn, Hull, on Thursday afternoon of last week, July 29. Dr. Elliot Washburn, superintendent of the Rutland Sanatorium, read a paper by the late Chester Bryant, an agent of the Haverhill Board of Health, on "The Incurable Consumptive." The second paper of the afternoon was by Dr. Francis G. Curtis, chairman of the Newton Board of Health, on "Some Inconsistencies in Dealing with Tuberculosis."

THE DENTISTS' DILEMMA.—In the issue of the *JOURNAL* for July 22, we noted the complication arising as a result of the enactment of the new dental registration law in this Commonwealth. As a result another meeting of the registration board was held on July 27, at which the additional examination required was taken by one hundred, of the two hundred and one candidates previously rejected. Of these, ninety-three were passed.

Massachusetts Medical Society.

FRANKLIN AND HAMPSHIRE DISTRICT SOCIETIES.—Wednesday, July 14, Franklin-Hampshire District Societies had a combined meeting and outing at South Deerfield. Little Franklin's baseball men scored a 10—5 victory over Hampshire on a field at the base of beautiful Mt. Sugar Loaf. Superintendent Dr. Charles E. Perry of the County Tuberculosis Hospital at Northampton read a paper covering the field and service of such hospitals and advocating a larger hospital unit on account of the expense. The state law relating to the establishment of sanatoria in towns of 10,000 or more population appears to work a hardship in this rural section. In the discussion which followed the following participated: Dr. J. E. Urquhart of Ashfield, president of the Franklin Society; Dr. H. G. Stetson, Dr. C. C. Messer, Dr. G. P. Twitchell, Dr. N. P. Wood, Dr. Charles Moline, and Dr. P. W. Goldsbury of Franklin; Dr. C. T. Cobb of Easthampton, president of the Hampshire Society; Dr. Christopher Seymour, Dr. J. G. Hanson, Dr. F. H. Smith, Mr. Clarence Hodgkins, chairman, and Mr. Frank E. Brooks of the County Commissioners of Hampshire County. Dr. N. P. Wood of Northfield moved that a committee be appointed including the presidents of both Societies to see what could be done to the effect that the hospital for Hampshire County might serve Franklin County as well, and the motion was carried. About fifty sat down to an excellent dinner at the Warren Hotel.

P. W. GOLDSBURY, M.D.

Miscellany.

THE MILK INDUSTRY.

REPORT OF THE BOSTON CHAMBER OF COMMERCE COMMITTEES.

THE medical profession will be interested in the report of the Committee of the Boston Chamber of Commerce which, as noted in these columns last July, has made an exhaustive survey of the milk industry in New England during the past year. The committee was composed of the following persons: John P. Bowditch, George H. Ellis, John C. Runkle, and Walter E. Smith, and it has had the assistance of several specialists. Sixteen hearings have been held in all the New England states, attended by 2500 farmers, representing between 70 and 80 per cent. of the milk-producing towns. These are the six recommendations made in the report:

1. The establishment of a standardized system of milk grading and labelling for all New England.

2. The establishment of country milk stations by producers in co-operation with local business men and railroads, where milk may be graded and processed and the surplus utilized in the manufacture of butter and cheese.

3. Bookkeeping by farmers for keeping accurate records of production costs and economizing farm operations. A co-operative arrangement is suggested.

4. Reform of present methods of railroad transportation, abolishing the leased car system and establishing uniform per-can rate.

5. Improvement of city distribution. Adoption of the ticket system, cost accounting methods, and the study of common problems by dealers in a co-operative organization.

6. Advertisement of the food value of milk and milk products, thus adding to the other improvements in marketing the important factor of publicity.

As regards the "ticket system" referred to in the fifth recommendation it may be said that the cost of delivery to the family might be reduced by use of the ticket system which has worked successfully in the West and in some cities of New England. The consumer pays \$1 or less for tickets, which he puts out each day in the empty bottles for the amount of milk and cream he wishes. This assures the dealer his money in advance, prevents loss by bad bills, and secures the return of bottles. This ticket system will enable the price of milk to the consumer to be raised or lowered in fractions of a cent.

A perusal of the full report by every physician will be time well spent.

Correspondence.

LOBAR PNEUMONIA.

WESTPORT, NEW YORK, July 29, 1915.

Mr. Editor: In Dr. Frederick T. Lord's article, July 29, 1915, page 154, I find the following: "In consideration of the development of pneumococci only at body temperature and their short viability outside the body, *contagion* must be regarded as the method of spread." This statement prompts me to affirm again, what I thoroughly believe, that for all patients, either imminently threatened with pneumonia, or already suffering from it, it is all important, whenever practicable, to have beechnut creasote, constantly vaporized in the sick room.

This may be readily done with the ordinary croup kettle filled with boiling water, to which a small quantity of creasote is added, as required.

Whether, or not, creasote, or creasotal, should be prescribed internally, is questionable.

In hospital wards, the reason, almost of necessity, we have increased mortality is because treatment with creasote inhalations cannot be properly carried out. In hospital private rooms, it is, of course, different. I have tried many methods of treatment in pneumonia, but have never seen any so efficacious as the one I recommend.

MEDICAL BROTHERHOOD FOR THE FURTHERANCE OF INTERNATIONAL MORALITY.

In last week's issue of the JOURNAL we noted the appeal and plan of Dr. S. J. Meltzer of New York for the formation of a medical brotherhood for the furtherance of international morality. It is announced that this organization has now been effected and the following are announced as its officers:

EXECUTIVE COMMITTEE.

Residents of the City of New York.

President, Dr. S. J. Meltzer, Member, Rockefeller Institute.

First Vice-President, Dr. Rufus Cole, Director, Rockefeller Hospital.

Second Vice-President, Dr. S. Josephine Baker, Director, Dept. of Child Hygiene.

First Secretary, Dr. Wm. J. Gies, Professor of Biological Chemistry, Columbia University.

Second Secretary, Dr. Harlow Brooks, Professor of Clinical Medicine.

Treasurer, Dr. Robert T. Morris, Professor of Surgery, Post-Graduate Medical School.

COUNCIL

Dr. Abraham Jacobi.

Dr. Robert Abbe, Surgeon to St. Luke's Hospital, Board, Bellevue Hospital.

Dr. J. A. Fordyce, Professor of Dermatology, College of Physicians and Surgeons.

Dr. Nellis B. Foster, Assistant Professor of Medicine, Cornell University Medical School.

Dr. S. S. Goldwater, Commissioner, Dept. of Health, Dr. Graham Lusk, Professor of Physiology, Cornell University, Medical School.

Dr. William H. Parke, Professor of Bacteriology, Univ. and Bell, Medical College.

Dr. John Allen Wyeth, President, New York Polyclinic.

HONORARY RESIDENTS.

Dr. Russell H. Chittenden, Director, Sheffield Scientific School, Yale University, New Haven.

Dr. W. T. Councilman, Professor of Pathology, Harvard Medical School, Boston.

Dr. W. C. Gorzas, Surgeon-General of the Army, Washington, D. C.

Dr. W. S. Halsted, Professor of Surgery, Johns Hopkins Medical School, Baltimore.

Dr. W. H. Howell, Professor of Physiology, Johns Hopkins Medical School, Baltimore.

Dr. Abraham Jacobi.

Dr. W. W. Keen, President, International Surgical Congress; President, American Philosophical Society, Philadelphia.

Dr. Edward L. Trudeau, Saranac Lake, New York.

Dr. James Tyson, Professor of Medicine, Emeritus, University of Pennsylvania, Philadelphia.

Dr. Victor C. Vaughan, Professor of Hygiene and Physiological Chemistry, Ann Arbor.

Dr. William H. Welch, President, National Academy of Sciences; Professor of Pathology, Johns Hopkins Medical School, Baltimore.

HONORARY VICE-PRESIDENTS.

Dr. J. J. Abel, Professor of Pharmacology, Johns Hopkins Medical School, Baltimore.

Dr. Herman M. Biggs, Commissioner, State Board of Health, New York City.

Dr. Frank Billings, Dean, Rush Medical College, Chicago.

Dr. Clarence John Blake, Professor of Otolaryngology, Harvard Medical School, Boston.

Dr. W. B. Cannon, Professor of Physiology, Harvard Medical School, Boston.

Dr. W. H. Carmalt, Professor of Surgery, Emeritus, Yale University Medical School, New Haven.

Dr. George Dock, Professor of Medicine, Washington University, Medical School, St. Louis.

Dr. James Ewing, Professor of Pathology, Cornell University Medical School, New York City.

Dr. Alice Hamilton, Expert on Occupational Diseases, Federal Bureau of Labor Statistics, Washington.

Dr. L. Hoktoen, Professor of Pathology, Rush Medical College, Chicago.

Dr. Howard A. Kelly, Professor of Gynecology, Johns Hopkins Medical School, Baltimore.

Dr. Robert G. LeConte, President, American Surgical Association, Philadelphia.

Dr. Rudolph Matas, Professor of Surgery, Tulane University, New Orleans.

Dr. William J. Mayo, Rochester, Minnesota.

Dr. Charles K. Mills, Professor of Neurology, University of Pennsylvania, Philadelphia.

Dr. John B. Murphy, Professor of Surgery, Northwestern Medical School, Chicago.

Dr. E. L. Opie, Professor of Pathology, Dean, Washington University Medical School, St. Louis.

Dr. Charles A. Powers, Professor of Clinical Surgery, Emeritus, University of Colorado, Denver.

Dr. W. L. Rodman, President, American Medical Association, Philadelphia.

Dr. G. E. deSchweinitz, Professor of Ophthalmology, University of Pennsylvania, Philadelphia.

Dr. Henry Sewall, President, Association of American Physicians, Denver.

Dr. F. C. Shattuck, Professor of Medicine, Emeritus, Harvard Medical School, Boston.

ADVISORY COMMITTEE, 102 MEMBERS.

Medical readers of the above are requested, if they are so inclined, to enroll as members. There is no membership fee. But voluntary contributions for the purpose of upholding the organization, distribution of literature, etc., will be gratefully accepted. Enrollment and contributions are to be sent to the Medical Brotherhood in care of

S. J. MELTZER, M.D.,

13 West 121st Street,

New York City.

APPOINTMENTS.

MONTEFIORE HOME.—Dr. Benjamin S. Klein of the Rockefeller Institute for Medical Research has been appointed resident pathologist of the Montefiore Home for Chronic Invalids in New York.

NEW YORK POST-GRADUATE MEDICAL SCHOOL.—Dr. Ward J. MacNeal has been appointed director of laboratories at the New York Post-Graduate School and Hospital to succeed Dr. Jonathan Wright who has resigned. Dr. Morris Fine has been appointed adjunct professor of pathologic chemistry and Dr. Richard M. Taylor adjunct professor of pathology.

UNITED STATES PUBLIC HEALTH SERVICE.—Dr. M. Sullivan has been appointed biochemist in the United States Public Health Service to engage in the study of pellagra at the Pellagra Hospital in Spartanburg, S. C.

RECENT DEATHS.

DR. EDWARD BEDLOE who died on July 24 at Philadelphia was born in 1848. Though educated as a physician and dentist he never engaged in practice but devoted his life to the United States Consular Service, having served as consul at Verona, Italy; Alexandria and Cairo, Egypt; and Amoy, China.

DR. CHARLES HARVEY SHATTUCK who died on July 26 in Malden, Mass., was born at Quechee, Vt., in 1863. He received the degree of M.D. from Dartmouth Medical School in 1881 and practised first at Ballardvale and later at Andover, Mass. He removed to Everett, Mass., in 1902 but lately had resided at Malden. He is survived by his widow, two daughters and three sons, one of the latter a practicing dentist in Everett.

DR. CHARLES F. P. BURCHMORE, of Boston, who died on July 27 at Winthrop, Mass., was born in 1864. He received the degree of M.D. in 1893 from the Baltimore College of Physicians and Surgeons, and was a member of the Massachusetts Eclectic Medical Society. He is survived by his widow.

Massachusetts Anti-Tuberculosis League

FIRST ANNUAL CONFERENCE, APRIL 1, 1915.

I.

THE ORIGIN AND AIMS OF THE MASSACHUSETTS ANTI-TUBERCULOSIS LEAGUE.*

By VINCENT Y. BOWDITCH, M.D., BOSTON,
President.

At the first anniversary meeting of the Anti-Tuberculosis League of Massachusetts, it may be well to reiterate the statement made a year ago, at the last meeting of the "Massachusetts Tuberculosis Conference." The League was an outgrowth of that Conference, which in itself was originated by our Boston Association and was formed for the purpose of spreading the knowledge of the work done by it throughout our State. The purpose of the League is to bring all of the various associations and affiliations into closer touch with each other, in order that by coöperation and coördination more efficient work can be accomplished than ever before.

Massachusetts has always been in the foremost ranks of anti-tuberculosis work, and the formation of this League is, in my opinion, a marked step forward in procuring greater efficiency of effort.

It would be impossible in a short space of

time even to touch upon all the many phases of the anti-tuberculosis work, but certain important points that have impressed themselves upon my mind I wish to emphasize now. I have spoken of the necessity of coöperation among all the increasing number of anti-tuberculosis associations in the state, in whatever special form of work each one is interested. Such meetings as we have here today must have their good effect in enabling us all to learn how each community is grappling with its own special problems. I am convinced that it is important to recognize the fact that, owing to varying conditions, each locality may have its own special way of dealing with the tuberculosis problems, and what may be a good method in one, may not be so suitable for another. The main fact should be that wherever work is being done the situation should be met with vigor and determination to control the ravages of the disease. The mere establishment of an anti-tuberculosis association which lacks the elements of patient, dogged perseverance in following up the work, will amount to little or nothing. Mere "flash-in-the-pan" enthusiasm is of no avail, and proof of determined effort in one direction or another to stamp out or at least control the disease wherever it arises should be insisted upon, as a *sine qua non* of membership in the League. For this reason, if our name means anything, we should have some standard of work which entitles an association to membership. This subject, I am glad to say, will be thoroughly brought out in our addresses today, and is of vital importance to the worth and efficiency of our organization.

Thus far, in many communities and not with-

* Read at the first annual meeting of the League in Boston, April 1, 1915.

standing the efforts of anti-tuberculosis associations, there has been a lack of proper response to the legislation which has been enacted during the past four years with reference to the establishment of hospitals for advanced cases in cities of 10,000 inhabitants or over, and for dispensaries in cities and towns of 10,000 inhabitants or over. At the time of writing, out of 35 cities in Massachusetts, but 16 have established hospitals, three or four of these having been founded by private means. The others are of municipal origin.

Of the 54 cities and towns of 10,000 or more inhabitants, 21 say they have dispensaries, the term being apparently somewhat elastic; for, up to the present, a decided difference exists in the scope and efficiency of those thus far established. The amendment of 1914 to the original bill for dispensaries now creates a standard which if followed will be a great step forward.

Fortunately, our newly-appointed Commissioner of Health has put himself on record as intending to see that the laws upon these matters are strictly enforced, and we hope to see during the next year those cities and towns, which have been laggards thus far, coming to the fore and adopting measures which are essential to the welfare of all. It should be the function of the members of our League throughout the state, so to influence public opinion by every means in their power that our Commissioner may be enthusiastically supported in his laudable endeavor to see that the laws are obeyed.

Wherever tuberculosis exists, we shall have to come face to face in a greater or less degree with one problem which is of great importance and to which my attention has been very strongly drawn recently, viz.: What shall be done with the incorrigible consumptive who, in spite of instruction, admonition, or threats, persists in disobeying hygienic laws and wilfully fails to do his part in lessening the danger of contagion?

At the meeting of the Eastern Branch of the National Association for the Study and Prevention of Tuberculosis, in Bangor, Maine, last October, a member of the Board of Health of Haverhill,—who, unfortunately, has recently died,—gave a most impressive account of his attempt to remove incorrigible consumptives from their homes. On account of the restricted powers of the Board of Health, he was continually hampered in his endeavors to control several cases by lawyers who aided the offenders, and, because of this, his hands were completely tied in the performance of what he knew was of paramount importance to the health of the citizens. The account of his various troubles and tribulations was interesting and even amusing, and tempted one to see only the ludicrous side of life, had not the underlying seriousness of the man convinced one that he had been dealing with one of the most difficult and serious prob-

lems which must be grappled with and solved if we desire success in our efforts to control this disease.

Drastring measures are always to be undertaken with extreme caution, and only when less strong means are unsuccessful.

In the case of tuberculosis, moreover, the fact of the long duration of the disease adds greatly to the difficulty of dealing with it in all its phases. With the acute infectious diseases, it is comparatively easy to seize upon a dangerous case and confine it closely for a comparatively short space of time. Not so with the consumptive, dragging out long months and years in the course of the disease: a fact which changes the moral aspect, as it were, of the question of dealing with such cases. For the welfare of our state, however, we are justified in demanding enlarged powers for our boards of health, by which sterner measures not inconsistent with kindness and regard for the feelings of others may be used for the enforced isolation of the incorrigible consumptive who persists, by careless and dirty habits, in making himself a source of danger to others. Lest there should be fear in the minds of some as to the justice of such summary procedures, it should be stated that amendments to existing laws have already been proposed by which the rights of patients will be amply protected before measures necessary for the public welfare shall be adopted.

Since 1912, four states have adopted laws for compulsory segregation for incorrigible cases: New Jersey, New York, Wisconsin and Minnesota; but there is a marked dissimilarity in the methods of legislation upon this important subject, and thus far one is left in doubt as to the comparative merit of the different laws passed in the various states.

The question has not infrequently been raised of late about the necessity of keeping up anti-tuberculosis associations in communities which have taken definite steps towards establishing local hospitals, dispensaries and other methods of overcoming the disease. It is my firm belief that the time has not yet come, and is not likely to come for many years, when such associations are unnecessary. In my opinion, they should be independent, as a rule, of all institutions which deal with the disease, but it should be their function to see that proper measures are adopted and enforced, and to act as constant aids in settling problems as they arise, both in securing legislative aid and in keeping facts constantly before the public. There is always danger, after certain important steps have been taken, that the public will believe that everything necessary has been done and that no further effort is needed. Inaction and the danger of falling into ruts may easily result from such an attitude of mind, and it is the function of anti-tuberculosis associations to counteract this tendency.

One other vital question for the public viz.: the more widespread establishment of open-

air schools and of so-called "preventoria," or special sanatoria, for the reception of children who are showing symptoms of debility, which may be the forerunner of subsequent disease, and even for those who have already shown undoubted evidence of tuberculosis.

We can safely say that it is gradually becoming the established belief that tuberculosis, often in latent form, in childhood is the forerunner, much more frequently than was formerly supposed, of active disease in adult life. The importance of proper attention to this phase of the question, therefore, cannot be overestimated.

The beneficial effect of open-air schools upon the health of children thus far shown should certainly encourage us to push this matter much more energetically than has been done up to the present. As a concrete example of this, I should like to mention a letter recently received from a teacher in one of our large cities, she having been a graduate from the Sharon Sanatorium, seventeen years ago, after a long, successful struggle against tuberculosis. A short time ago, she wrote, not only of her own good health and almost interrupted seventeen years of teaching, but she added the significant words, "I not only know the inestimable benefit of fresh air upon myself, but I am constantly teaching it to my pupils. During the past winter I have had the windows of the school rooms almost constantly open. During epidemics of 'colds' among most of the schools in Lowell, this winter, not one of my children has been out of school or incapacitated by a 'cold'." a statement which not only stands for the value of fresh-air treatment, but shows us the value of sanatoria as schools in themselves for teaching people the simple but important laws of hygiene: the strongest factor we know in the practice of what we call "preventive medicine."

A school has been established for the tuberculous children who are patients at the state sanatorium at Westfield, Mass.—the only one of our state sanatoria to adopt the plan. During the past year the Boston Consumptives' Hospital has opened a school at Mattapan, and the state school at Canton for crippled children should be included in this list although not strictly confined to cases of tuberculosis. At the Sharon Sanatorium,—a private institution,—hitherto intended for women or girls only, a new department is to be established through the generosity of a relative of a former benefactress, and plans are now developing for a building to be devoted to the treatment of boys and girls under the age of fourteen who are showing symptoms of tuberculosis, especially of the pulmonary variety. It is planned to combine a certain amount of school work with the treatment, which, when done, will mark a new departure in the methods of private sanatoria in this part of the country.

The foregoing subjects are a few of the many important ones which come up in any consideration of anti-tuberculosis work. Proper housing of the poor, and factory supervision are matters

which can be touched upon here merely to urge their vast importance and the necessity of concerted action to ensure proper enforcement of existing laws.

In closing I can only reiterate my firm belief that by coming together in this way, we shall by patient, persistent and energetic work accomplish much towards limiting the ravages of this disease, with the prospect of gradually relegating it to the class of preventable ills of the human race.

II.

WHAT THE ANTI-TUBERCULOSIS ORGANIZATIONS CAN DO TO HELP THE STATE DEPARTMENT OF HEALTH.

BY ALLAN J. McLAUGHLIN, M.D., BOSTON.

Commissioner of Health, Massachusetts State Department of Health.

I WONDER if the individual members of the Massachusetts Anti-Tuberculosis League realize the full possibilities of their organization in the prevention of tuberculosis. The underlying motives that bring most of us into organizations of this kind are usually those of charity, humanitarian feeling and sympathy with suffering, rather with the idea that suffering is centered in the individual. This is perhaps our motive at first. But we can take no part in a movement of this kind for any length of time without realizing that the individual after all is only a small part of a great problem, and that the point of view must be that of the community rather than the individual. The care of the individual of course sometimes lies along parallel lines with the prevention of the disease, but after all the keynote of prevention is control of the individual.

Now the health officer in many cases has been accused of being cold-blooded and mathematical. I have been in countries during epidemic times where we have been accused, and I think we should have had to plead guilty, of neglecting the individual patient because we did not consider that our function; and although it was unfortunate that there were not officers enough to give that individual care to the patient, as responsible health officers we felt it was justifiable to neglect the individual for the good of the community. Fortunately, in tuberculosis, the two lines of care of the individual and prevention of the disease run parallel, so that we have no need here to neglect the patient in order to carry out our line of preventive work.

The health officer's duty today is not only to prevent disease but to keep people well. That is, he works along the line of preventive medicine, and the fact that he has been called mathematical and cold-blooded is accentuated by the fact that he bases his work on vital statistics. It is mathematical to that extent, and perhaps he is cold-blooded. He has to adjust his finances

to the needs of the situation. A couple of years ago a good friend of mine and a health officer said, "It would be better for the city to spend \$150,000 than to have one death from typhoid fever." It was beautiful as sentiment but rather expensive. A health officer must be a business man. He must talk to business men; get his money from business men. He must show them that he spends his money according to the needs of the situation.

Again in tuberculosis we are fortunate. We need no justification for spending large sums of money. A health officer looks first at the death rate. He finds that 80% of his mortality is due to six or eight big causes. There are two things that will justify him in attacking those causes. He finds those two things are: first, is it a big enough factor to consider; second, is there any hope of getting any result for the money spent? You will excuse me for speaking in this business-like way. I have some sentiment but I have to look at this other side of it. That is the way health officers must look at it. Tuberculosis is one of our great big problems. In total deaths it is one of the greatest causes of our general death rate. Further, it is not a hopeless proposition but is one of the most hopeful with which we have to deal.

There are two general lines of activity that promise large returns. I may seem cold-blooded, but I apologize for that to cover the entire talk. First, to get control of the open case of tuberculosis for as many months as possible prior to his death. We know that he is far more dangerous in the last months of his illness than he is when the disease is in what we call the second stage. Second, to find out and get control of the incipient cases to prevent them from becoming open cases. Those two lines of activity, if pursued under proper direction, with proper diligence and enthusiasm, will cut the death rate from tuberculosis in two in this state inside of five years.

Now how can this be done? We have on the statute books today two excellent laws that make this result possible. The splendid state sanatoria are struggling with the burden of open hopeless cases which prevent the admission of the hopeful incipient case that might be arrested and cured, so that in spite of the splendid efforts of the board of trustees of hospitals for consumptives they are not doing what might be done in the way of prevention. That is, they are doing neither one of these two things. They have not bed capacity enough to take care of the fatal cases in the last months of their illness, nor should they be expected to do such a thing. This is the function of the local hospital. On the other hand, the admission of these cases, which is almost inevitable under existing conditions, prevents the admission of the hopeful case which might be prevented from becoming a hopeless or open case. As it stands at present, the waiting list is so long that the incipient case, which is hopeful at the time he is found, cannot be ad-

mitted until he is beyond the point where he could be saved.

The hospital law provides that cities and towns shall build tuberculosis hospitals to care for their consumptives at home. It works two ways. In the first place it relieves the state sanatoria for the purpose in which they can do the greatest good in this problem—that of taking care of the incipient cases, and it affords the dying consumptive the care and control that is necessary to prevent him from being a menace,—near his home, where he is likely to stay. I will not go into that problem any further. Other speakers will take it up. You know as much about it as I do.

The other law is the dispensary law. In order to follow the second line of activity, to find the cases early and get them under control, to follow up the arrested cases and see that they stay cured, to give proper advice to the tuberculous patient and to his family, it is necessary to have a proper dispensary. The dispensary law provides that all cities and towns of 10,000 inhabitants or over shall have these dispensaries.

One great function that this Anti-Tuberculosis League can perform is to assist in the building of these hospitals. There are certain groups of towns, perhaps four or five towns adjoining, no one of which is large enough to support a tuberculosis hospital but which can be combined in a plan to build a joint hospital. I know of no agency that would be as effective as the local anti-tuberculosis society in effecting this result. Where this result is desirable we have found it to be very difficult to obtain. We find that three or four towns, we will say from 5,000 to 10,000 or 12,000, could, with benefit to all, build a joint hospital. It is good business. It is more economical to conduct a 50-bed hospital than 5 10-bed hospitals. It should be done. We find it is difficult to effect because town A proposes to town B and town B believes that town A is trying to put something over on them. Towns C and D are in the same category and the project falls through. It is in such matters as these that the local anti-tuberculosis societies working together as a unit can stimulate that joint co-operation to build a hospital to take care of four or five such communities.

The other great function that may be performed in the way of aiding the State Department of Health in this campaign against tuberculosis is in the establishment of tuberculosis dispensaries. Under the law before mentioned, if you allow the cities and towns to establish their dispensaries they have only one idea—to avoid paying the fine. They have not any particular interest in what kind of a dispensary, or in what kind of rooms are furnished, or what kind of care is given, or how many cases are found. In fact the fewer found the fewer that will have to be taken care of. I regret to say that this attitude is not uncommon. It is necessary to have some stimulus to arouse public opinion to the point where they will do their duty in regard

to the tuberculosis problem, and the local anti-tuberculosis society can do more good in this way than any other, even more in this way than they can in the establishment of hospitals—not only to see that there is a dispensary but to see that it is the right kind of a dispensary.

The previous speaker, the chairman, Dr. Bowditch, said very rightly that the necessity for these organizations would not disappear for some time. I do not believe that any of us will live long enough to see the necessity disappear. Personally I would place upon them the necessity of policing the local city and town governments to see that they carried out the plans in regard to tuberculosis and did their full duty to the public. In some instances they will have to establish the dispensary themselves and finance it. In other instances the municipal council will furnish the funds to establish the dispensary, but I do not think that relieves the anti-tuberculosis society of its plain duty to see that it is a proper dispensary, and to work with the local board of health. When the board of health will not establish a dispensary it becomes the duty of this organization to establish such a dispensary and to finance it. If they cannot get the local board of health to take charge of it, then they have the saddle on their back and they must carry the load. I hope that appears to you as great a responsibility as it does to me—that responsibility I am going to ask the League to place upon you.

I might say a word in regard to team work. We are setting you the example here in Boston. We have three great agencies working along similar lines and the team-work is an example of what can be done—the Trustees of Hospitals for Consumptives, State Department of Health and the Anti-Tuberculosis League. I can assure you that we have the finest kind of team work. We are going to get results. I ask you to try to establish the same kind of coöperation with your local board of health and your local city government.

In regard to the enforcement of the law it seems to me there would not be any justification for having these excellent laws if we did not enforce them. We have given cities and towns to July 1 to establish dispensaries, and until September 1 to comply with the law in regard to hospitals.

III.

THE PRESENT SITUATION IN REGARD TO LOCAL TUBERCULOSIS HOSPITALS.

By JOHN B. HAWES, 2d, M.D., BOSTON.

Sec. Trustees, Massachusetts Hospitals for Consumptives; Assistant Visiting Physician, Massachusetts General Hospital.

WISE legislation should be the result of a strongly developed public opinion. Sometimes it is in advance of such opinion and at other

times it lags behind. This is shown in a striking way in the working out of the tuberculosis hospital law known as the Isolation Hospital Act, which was passed in 1911. This law requires every city in this Commonwealth to have a local tuberculosis hospital or its equivalent. It was amended in 1912 so that private incorporated hospitals might come under this act. In some cases, such as Boston and Cambridge, this act was quite unnecessary, as public opinion in both these cities, and elsewhere, had already realized the need of a local tuberculosis hospital and had brought about the construction of such an institution. In other instances, comparatively few, it was the passage of this law which aroused public opinion into activity and resulted in the immediate opening of such a local hospital. In other instances the law has apparently been allowed to remain a dead letter until recently; a compliance with it has been evaded by various methods too well known to require enumeration.

At the present time there are in Massachusetts, 54 cities. Of these 54, 18 have local tuberculosis hospitals, each of which has been approved by the State Tuberculosis Commission under the terms of the so-called Subsidy Act. The local hospitals in these 18 cities provide 1042 beds, to which total can be added 40 more from the recently opened Hampshire County Sanatorium, making the total 1082. The total number of cities that have really complied with this law, in that although having no tuberculosis hospital of their own they have made arrangements with nearby cities which are provided with such institutions, would bring the total up considerably higher. Cambridge, for instance, with 88 beds, receives patients, mostly women, from Belmont and Arlington. Fitchburg, with 29 beds, occasionally receives patients from Shirley, Leominster and other nearby towns. Lawrence, with 88 beds, has no extra room for men, but plenty of extra beds for women, and accommodates nearby towns. Lynn, with 60 beds, does the same. The Sassaquin Sanatorium, a privately endowed institution in New Bedford of the highest class, takes care of New Bedford primarily but also accommodates the surrounding towns in the Cape district. Pittsfield does the same. Salem, with 36 beds, has plenty of room for both men and women. For some reason or other, which I have been unable to understand, Salem has placed an almost prohibitive price for board so that nearby cities and towns have not been able to avail themselves of the empty beds in this hospital. Waltham has 17 beds, with vacancies for both men and women, and receives a certain number of patients from both Newton and Watertown. The recently opened hospital in Worcester, with 55 beds, is unable to receive other than local cases. Fall River, with 56 beds, is kept full with local patients.

How far our present health department will go in allowing such combinations as mentioned above cannot be foretold. Each case naturally must be decided upon its individual merits. At

the present time, for instance, Newton, one of the wealthiest cities in the state, has absolutely no accommodation for its tuberculous patients but sends them to the Waltham Hospital or depends entirely upon our state sanatoria. I am quite safe in stating that this situation will not be allowed to continue and that Newton will be forced to build a hospital of its own, and will not be allowed for a much longer time to evade its just responsibilities. Brookline has no tuberculosis hospital worthy of the name. I believe that here also no combination will be allowed with any other town. On the other hand, Cambridge has for some time taken care of patients from Arlington and Belmont. This arrangement seems to work very satisfactorily and will probably be allowed to continue. Recently Melrose has been making tentative arrangements with Waltham and Lynn to care for its tuberculous patients. I am sure that here no permanent arrangement of this sort will be allowed, as it is illogical in every way. On the other hand, were Melrose to suggest a combination with either Malden or Everett I know that it would be looked upon with favor. There are 18 cities with a total population of 553,000 that have no local tuberculosis hospitals. Lowell, with a population of 106,000, heads this list. It is to be hoped that this city will not be allowed very much longer to continue in its unenviable position. Brockton has so far taken no action in regard to this matter, but depends upon the state sanatoria almost entirely. Aside from this, Brockton has shown commendable activity in its tuberculosis work. Malden has appropriated a small amount and has prepared plans; nothing further, however, has been done. At present patients from this city are sent to Somerville or Cambridge. Newton and Taunton have both prepared plans, but have done nothing further. Everett has a tuberculosis hospital nearing completion. Quincy, Chelsea, Gloucester and Marlboro have prepared plans, but have done nothing else. Revere has made a definite arrangement with the city of Lynn for the care of its tuberculous patients. This is a perfectly logical procedure and will doubtless meet with approval. North Adams, Beverly and Attleboro are considering the matter, but have taken no action; while Melrose, Woburn and Newburyport have as yet done nothing. Among the larger towns which will probably be called upon by the health department to provide themselves with proper tuberculosis hospitals, Brookline, with 27,000 inhabitants, stands first on the list. Brookline town officials seem to labor under the curious impression that there is no tuberculosis in their midst and that they have no tuberculosis problem. It is comparatively easy to dispel this idea, however. Leominster, Peabody, Gardner, Milford and Adams have done nothing. Gardner, however, has a most active and excellent health board and tuberculosis association, and at present seems to handle its local problem in an admirable and efficient manner. Adams has re-

cently taken up the matter, and is preparing plans. Framingham has as yet done nothing. Clinton is fortunate in having a privately endowed tuberculosis hospital of the very highest class. Weymouth, Watertown, Southbridge, and Plymouth have done nothing. Weymouth plans to coöperate with Quincy; Watertown might well coöperate with Waltham. Plymouth is in urgent need of local accommodations of some kind. Webster, a manufacturing town of 11,000, should have some provisions for its local cases. Methuen, Wakefield and Arlington, 11,000 inhabitants each, send their patients to Lawrence, the State Sanatoria, Somerville, and Cambridge, respectively. Winthrop at present sends its patients to Lynn.

This is an outline of the present situation with one exception, which is the question of the county tuberculosis hospital. Last year a bill was passed allowing Hampshire County to construct a tuberculosis hospital. This has been done at Leeds, not far from Northampton. A bill is before the present Legislature, which has been reported favorably, to allow Barnstable County to do the same. Next year it is very likely that Franklin County may put in a similar bill. Each of these counties is distinctly suited for the county hospital idea, there being no large cities but only small, comparatively isolated towns in these districts. This is particularly true of Barnstable County. The difficulty which has arisen so far, and it is apparently a real one, lies in the fact that the present Hampshire County institution is called a sanatorium and is endeavoring to do sanatorium work. This, of course, is not what it was intended for, and is not what is desired. It is, however, quite natural that the superintendent should prefer to deal with incipient cases rather than to take the hopeless and dying ones. I hope very much, however, that it will be made clear and definite that the county hospital, wherever it exists, is simply to take the place of local hospitals and is not intended, in any way, to supplement our state sanatoria.

At the present time the outlook is distinctly encouraging. The greatest factor for good in the present situation is our State Health Department under the strong and aggressive leadership of Dr. McLaughlin.

Dr. McLaughlin, with the backing of an able health council, has wisely decided that this law, requiring local tuberculosis hospitals in every city and in certain towns must no longer remain a dead letter. He has put the proper machinery in motion to see that this law is enforced. He is using the milder methods of persuasion wherever possible, but is apparently fully prepared to use stronger measures in certain instances, too well known to require mention. The result of this activity on his part should mean that in a comparatively short time our state sanatoria at Rutland, North Reading, Lakeville and Westfield will be sanatoria in every sense of the word, where patients only are

received who are physically in such a condition that they can be benefited by real sanatorium treatment, and mentally and morally so constituted that they can coöperate with the efforts of the state to make them well and to restore them to their former place as useful citizens. Our local hospitals, as a part of this plan, will then care for far advanced cases, patients who should be near their relatives and friends, unruly, ignorant and incorrigible patients, who are not suited to our state sanatoria, and emergency cases of whatsoever kind.

Dr. McLaughlin already has the strong backing of the medical profession in his endeavors; to this should be added the sincere, earnest co-operation of every citizen of this Commonwealth.

IV.

LOCAL TUBERCULOSIS DISPENSARIES.

BY WALTER G. PHIPPEN, M.D., SALEM, MASS.

Director, Salem Tuberculosis Dispensary.

You all know that Massachusetts now requires all cities and towns with a population of 10,000 or more to maintain a tuberculosis dispensary. In order that we might know how many cities and towns were complying with this act and what their dispensaries were like, your committee sent out a questionnaire to the fifty-four cities and towns that were required to have a dispensary. The answers to this showed that only twenty-two out of fifty-four have such a dispensary. These differ in many respects. Some are controlled by local boards of health, some by local anti-tuberculosis societies, and some by special boards of trustees. Some are associated with general hospitals, some with local tuberculosis hospitals and some are independent of either. Some have nurses or a nurse connected with them and some have not. Some are open one hour a week. Some are open every day. Last year's legislature thought it wise to standardize these dispensaries and gave that power to the state department of health. This department wisely determined that the standard should not be too high, so that it should not prove a hardship to any town, but that at the same time it should be complete in the fundamental things. It has therefore issued a circular of minimum requirements, and ordered that they must be complied with before July 1. At the present time only four of the twenty-two already in existence fulfil these in all respects.

Apparently this order has caused some confusion and one might almost say consternation among the thirty cities and towns that have no dispensary. This is most noticed in the smaller towns that have or think they have only a few cases of tuberculosis in a year, and that therefore they do not need a dispensary. I think this idea comes about from an insufficient knowledge

of what a tuberculosis dispensary is and of the need it fills in a community. I propose, if I can, to show you what constitutes a good working dispensary for a small city or town and what work it should do.

In the first place let us clearly understand that there are two distinct types of dispensaries.

1. A clinic solely for the examination and treatment of patients having, or suspected of having, tuberculosis.

- (a) The tuberculosis department of a large general hospital.

- (b) The out-patient department of a tuberculosis hospital.

2. An examination clinic in connection with a local agency for all anti-tuberculosis work.

The first type is found in the larger cities and towns and is most adapted to their needs. I shall not consider this type further.

The second type of dispensary should be the center of activity of all local anti-tuberculosis work. It should do more than offer diagnosis and treatment. It should serve as a general information bureau for tuberculosis.

Such a dispensary may be managed by the local board of health or by the anti-tuberculosis association or by a combination of both. In any event both these organizations should work in perfect harmony. There seems to be no good reason why a group of adjacent small towns should not combine in maintaining a common dispensary.

The first requisite of a dispensary is a nurse or social worker, or, as I like better to call her, an instructive nurse. About this instructive nurse the whole fabric of the dispensary is constructed and without her it is of absolutely no value. She need not necessarily be a trained hospital nurse, but she should be familiar with tuberculosis, not only as a disease but as a social problem. She should have at least some training in social service work, and should be able to inspire confidence in patients and officials as well. She must assume the initiative in the tuberculosis work of the community, and must be forceful, stimulating and tactful.

The next requisite is the headquarters. Two outside rooms are required, a waiting room and an examining room. They should be situated in a reasonably quiet, central part of the town. They need not be large but they must be light and airy. Two rooms of this sort in an office building can usually be obtained for a moderate rental, say \$20 or \$25 a month. Not much furniture is necessary to start with. A desk and chair for the nurse, a settee or few chairs for the patients and a chair or stool in the examining room. A tactful instructive nurse can usually get this furniture donated.

The next requisite is a physician. He must be able to recognize tuberculosis in its early stages, be a willing worker, and should be interested in the social side of the disease. One examining physician may suffice at first, but I believe

there should be a medical director and several examining physicians.

The hours during which the dispensary should be open may vary in different localities, but a great deal of care should be used in their selection. Due consideration should be given to the physician's time; otherwise you will not get your staff to come willingly. Also due consideration should be given the patient's time; for instance, a day hour should be arranged to accommodate the school children, because you will have more of them to examine than any other class of patients. The night hour is necessary for arrested cases that are working and for suspicious cases that are working.

If the dispensary is to be of lasting value a careful record of every case must be kept. The general scheme of records, I think, should be uniform throughout the state. In the first place there should be a general card index of all the cases that have been reported to the dispensary. These should be arranged alphabetically and should be numbered. Each card should have a number, which should refer to a folder in which should be kept a history card containing the family, medical and housing history, together with a record of the physical examinations, a nurses' record or social history card, and any letters or notices or information concerning this particular case. These should be filed numerically. A street index should be kept showing every house in which a case of tuberculosis exists, filed alphabetically by streets. It is also well to keep a street index of houses where death has occurred. The history cards are standard Library Bureau cards and can be obtained for about \$12 a thousand. The other cards are also standard and at a less price. I should be glad to show samples of the cards we use to any that are interested.

The addition of a pair of scales for \$12, a few clinical thermometers for about \$4 a dozen, paper napkins \$.75 a thousand, sputum cups \$.635 a thousand, diet lists and leaflets free, and your dispensary is established.

The next question is, what are you going to do with it? It is one thing to establish a dispensary and another to use it. You mustn't expect the patients to walk into the dispensary of their own free will. They will have to be sent, I might perhaps better say, brought there. In short, the dispensary must be fed.

Patients should come through the following agencies:—

1. The local anti-tuberculosis society.
2. The local physicians.
3. The school physician and nurses.
4. Charitable relief organizations.
5. Friends of tuberculous patients.
6. Hospitals (including state sanatoria).
7. Personal applicants.

I put the local association first, because if there is one in the town it automatically provides the machinery for feeding the dispensary.

In many cities and towns the dispensary will doubtless be managed and controlled by the association, and I think every dispensary should have a volunteer association working in perfect harmony with it.

Do not be downhearted if the physicians do not make full use of the dispensary at first. Some physicians, I am sorry to say, feel that they will lose control of their patients if they send them to the dispensary. This is not so and should not be so. The physicians should be given every opportunity to keep in touch with their patients, and pains should be taken to inform them of the results of the examination. If you are patient and do not try to force the physicians to use the dispensary you will find that in time they will be ready and eager to coöperate.

The school physician and his nurses are very important contributors to the dispensary and should supply a very large proportion of the cases. They are in a position readily to discover the anemic and under par children and have sufficient authority to get them to the dispensary. This more or less routine examination is the only way to discover early cases among children, and we all know what good results are to be expected in their treatment.

The various charitable and relief organizations, including labor organizations, should be urged to make use of the dispensary. They may be expected to offer a large number of suspicious cases at least.

One of the most hopeful signs of the educational value of the work is the number of patients brought to the dispensary by old tuberculosis cases. Many new cases are discovered in this way.

If there is a general hospital in the town it will be very glad to make use of the dispensary and will soon be found to recommend all of its tuberculosis patients there. Notice is now sent to every board of health and local society whenever a member of that community leaves the state sanatoria. These should be immediately reported to the dispensary, and they should be looked up and made to report regularly. This is one of the most valuable functions of the dispensary—keeping track of ex-sanatoria patients and keeping them up to the treatment.

In mill towns and cities and in those places that are conducting an active educational campaign personal applicants will be numerous. These applicants may be expected to increase from year to year as the value of early diagnosis is spread among the multitude. In Salem five years ago only a very few applied; last year 54 out of 144 applied of their own accord.

A tuberculosis dispensary differs from any other kind of a dispensary in that every case admitted is always on the active list; even in case of most deaths the family must still be followed, especially if there are children. Therefore the criticism that because a town has only a few cases reported in a given year it does not need a

dispensary, will not hold water. The dispensary is needed because of all the accumulated cases of the past and the acquisitions of the future. Moreover, one new case of tuberculosis may mean ten or twelve additional examinations. If a town has three cases reported one year it may have sixteen the next, as actually happened in one of our towns that has no dispensary. The actual number of cases reported is by no means an accurate index of the number of cases of tuberculosis in the community. In Salem last year we had 114 new cases reported, while during the same time we had 208 cases on our active visiting list, and made 281 examinations at the dispensary. In one town, during a given series of years, seventy-five per cent. more cases died than were reported. Remember your dispensary must keep track of and re-examine all suspicious cases, all ex-sanatoria patients and all children in tuberculous families. This I think may lend a different aspect to the need of a dispensary in some communities.

I have said that the dispensary must do more than examine and treat. It must follow up each patient by means of its instructive nurse. This, I again impress upon you, is the most important part of your work. Let us consider some of the things the nurse will be called upon to do:—

1. Investigate the housing conditions and recommend needed changes.
2. Interview the employer.
3. Provide an outfit for the patient to go to a sanatorium.
4. Provide temporary means of treatment while they are waiting admittance.
5. Provide additional food such as milk and eggs.
6. Obtain the dependent mother's pension.
7. Secure permanent relief for the family.
8. Bring the family to the dispensary for examination.
9. Arrange for the treatment of other illnesses found in the course of these examinations, such as tonsils and adenoids.
10. Obtain the proper orthopedic care for the bone and joint cases. This includes splints, dressings and other apparatus, which requires no end of detail work.
11. Secure proper employment for incipient and arrested cases. This requires also the co-operation of the medical director, who should be the final judge of the fitness of the work.
12. Occasionally cases will be reported by the lower courts, not only for examination, but in conjunction with the probation officers on probation. These cases must regularly report at the dispensary or be seen at home, or in the local hospital, by the nurse.
13. She will be called upon to answer innumerable questions from patients, friends of patients, officials, organizations, ministers and social workers.

These one might call the routine things that she must do and a few cases will give the nurse

plenty to think about if she is new at it. On the promptness and tact with which these things are accomplished depends in a great measure the value of the dispensary.

The amount of help, advice and encouragement given in each case is limited only by the ingenuity and initiative of the instructive nurse. No doubt some physicians will tell you that they can do these things as well as the dispensary. Perhaps they can or could if they had the time, but they haven't the time to give to the necessary details. After the dispensary has handled a few cases demanding much thought, persuasion and actual labor, you will find the physicians very willing to avail themselves of its services.

I have spoken already of the records. I only further desire to say that they must be kept up to date. The examination must be recorded at the time it is made. The story of the housing must be written up immediately. The record of the nurse's visit must be written as soon as it is completed. Memory should not enter into them. The records are of value only in so far as they are accurate and original. I wish to speak particularly of the street index. In this index are kept alphabetically, according to streets, a list of houses in which there are actual cases of tuberculosis. The value of this is perhaps particularly impressed upon my mind because of the help it gave us in hunting up our cases after our great conflagration. By taking out the cards of the burned streets we had an accurate list of all the cases that had been burned out immediately available. With this list we went through the various camps and places of refuge the day after the fire and removed our cases to a special tuberculosis camp, thus in a measure minimizing the danger of spreading the infection. A special card catalogue of cases coming regularly to the clinic for examination is useful in rounding up delinquents.

I think these facts will show to any one who will think about them that there is need of a dispensary in every one of these cities and towns, or at least in groups of the smaller ones. The question whether the local Board of Health or the Anti-Tuberculosis Association should establish and maintain the dispensary is a question that must be solved in each community. There is much to be said in favor of both. Where there is a local anti-tuberculosis association that is active, much of the preliminary work will already have been accomplished, and if the board of health of such a community elects to establish the dispensary it should at least allow the active workers of the local society to share in its operation. In no case should there be a reduplication of effort. If a local society has a capable instructive nurse she should be made the dispensary nurse. In like manner the interested physicians should be put upon its staff. It must, however, be remembered that the boards of health have the authority to enforce rules and regulations, which a volunteer society has not.

In Salem the Dispensary has always been maintained by the Anti-Tuberculosis Association, and has been dependent upon voluntary contributions, except supplies of sputum cups, carbolic acid, etc., which are supplied by the Board of Health. The Board of Health has, however, always given its hearty coöperation and support, and the two have worked harmoniously together. The Dispensary came by a process of evolution as the work grew. A few interested people, a little money, an instructive nurse, a system of records, a class, small permanent quarters, regular hours, and our Dispensary was established. This process took three years. I hope that what I have said, brief as it is, will show these communities the need of a dispensary and will help them to establish one in three months.

V.

FIRST ANNUAL REPORT OF THE MASSACHUSETTS ANTI-TUBERCULOSIS LEAGUE.

By SEYMOUR H. STONE,
Secretary.

ORGANIZATION.

The need for closer coöperation among those engaged in the tuberculosis campaign of the state having become apparent to the Boston Association, at the invitation of this Association a committee of those interested met on January 8, 1914, for the purpose of organizing an Anti-Tuberculosis League. There were present at this meeting 16 persons from different parts of the state.

The form of organization planned by this committee was presented at the meeting of the Massachusetts Conference on Tuberculosis held March 26, 1914, to which the Anti-Tuberculosis Associations of the state were asked to send delegates. Twenty-two such delegates were present from 13 different cities and towns. A constitution and by-laws were adopted, officers and executive committee were elected and the League formally launched.

PURPOSE.

The purposes of the League are:

To keep the anti-tuberculosis organizations of the state interested in the fight against tuberculosis and informed as to the methods being employed by the state and local authorities.

To assist anti-tuberculosis associations and similar organizations in planning and carrying out local campaigns.

To help organize anti-tuberculosis associations and committees in communities needing them.

To arrange conferences for the discussion of tuberculosis problems.

To secure proper and oppose unwise legislation for the relief and prevention of tuberculosis.

MEMBERSHIP.

Anti-tuberculosis associations and similar organizations may become members of the League upon application to and election by the executive committee. Such associations are entitled to one delegate in the League, and an additional delegate for each 100 bona-fide members. At least for the present no dues will be expected from these associations, but it is hoped that they will see their way clear to contribute something toward the expenses of the League.

All persons interested in the objects of the League may become members by the payment of \$1.00 per year.

The present membership consists of 34 organizations; 22 of these are anti-tuberculosis associations, eight are district nursing associations, two are committees of women's clubs, one is a Red Cross society, and one a committee of associated charities. In addition to these the League has four individual members. Only eight anti-tuberculosis associations in the state have not become members.

COMMITTEES.

Besides the Executive Committee, the League has seven sub-committees, which, since January 8, 1914, have held 20 meetings.

Legislation. The campaign against tuberculosis being so largely dependent, of course, on adequate laws, the League has, during its first year, paid close attention to legislation.

In the spring of 1914 our Legislative Committee made a study of 38 bills before the legislature, while this year it has considered 23 bills.

The chairman of the Legislative Committee and the secretary or some other member of the League has usually presented to the proper committee of the legislature the views of the League on these bills.

The local associations have then been informed of the action taken by the League on the most important of these bills and urged to support such action if they could.

Local Associations and Affiliated Societies. This sub-committee has corresponded with organizations, and in some instances interviewed individuals or committees in Lynn, Milford, North Adams, Waltham and Greenfield for the purpose of starting some form of anti-tuberculosis work. In one other community the Committee is hoping to be able to coördinate already existing work. The Committee has also helped in starting organizations in Gloucester, Beverly and Lowell, and is ready to render similar service in any other community interested in the stamping out of tuberculosis.

Local Dispensaries. The present field of operation for this Committee is in those cities and towns which have 10,000 inhabitants or over and which are therefore required by law to maintain a tuberculosis dispensary. A study

of these communities, by means of a questionnaire, disclosed the fact that 33 of the 54 admitted having no dispensary, the remaining 21 stating that they had one in some form.

The State Department of Health has now required these delinquent cities and towns to comply with the law and establish dispensaries before July first of this year, and many of them are earnestly endeavoring to meet this requirement.

Local Hospitals and Local Boards of Health. According to information gathered by this Committee 16 of the 35 cities have complied with the law by providing a tuberculosis hospital. In addition to these, two towns and one county have such hospitals. Another county, Barnstable, is seeking permission by legislation this year to establish a hospital. The local hospital situation is, on the whole, encouraging. Many of the remaining 19 cities are either building or have plans under way. The State Department of Health has given these cities until September first of this year to comply with the law which was passed four years ago.

Our Committee has gone on record as favoring the plan adopted by Wellesley and several other towns in combining to employ jointly trained health officers, and urges its adoption by other groups of towns.

Publicity. The work of this Sub-Committee is educational. A small card exhibit, consisting of suitable literature printed in the foreign language common to the section to which it was to be sent was accepted for display in 75 public libraries of the state. A book of "Don't Cards," printed in 19 languages, was presented to six large libraries and 24 anti-tuberculosis associations.

Two printed leaflets were sent out as bulletins for publication in 54 foreign newspapers in the state.

The press bulletins of the National Association for the Study and Prevention of Tuberculosis, which are issued approximately every three or four weeks, have been sent regularly to a list of 245 newspapers in the state. Three bulletins of our own have also been given to these same newspapers. Nine hundred copies of the proceedings of the Massachusetts Conference on Tuberculosis have been sent to those interested in this subject.

The educational campaign has been still further aided by talks by officers of the League and physicians who have given generously of their time.

FINANCES.

Red Cross Christmas Seals. The League was this year appointed state agent for the sale of Red Cross Christmas Seals, the territory including the entire state except Berkshire County.

One hundred and fifteen sub-agents were appointed by the League to sell seals in this terri-

tory. Most of these were anti-tuberculosis associations, district nursing associations and committees of women's clubs. As a result of this campaign, 1,827,982 seals have been sold, the receipts amounting to \$18,279.82. Of this sum 82½% or \$15,080.85 is distributed among the anti-tuberculosis associations of the state for use in their local work; 10% or \$1,827.98, goes to the National Association for the expenses of the campaign and the support of the National Association; and 7½% or \$1,370.99, for the use of this League, out of which the cost of carrying on the local seal campaign must be paid.

The financing of the League is one of the serious difficulties that we have to meet. Since we cannot solicit in communities which already have anti-tuberculosis societies, our territory is naturally limited, and suggestions as to how we shall solve this problem will be very welcome.

Attention should be called to the assistance rendered the League by the Boston Association, in addition to the \$500 donated by the Boston Association to the League, it has given without charge the use of its office, which means rent, light and telephone service, and the services of its office force.

In looking back over its first year's work, we feel sure that the League has fully justified its existence and that with the broadening field that lies before it, it well merits your continued support.

VI.

REPORTING CASES OF TUBERCULOSIS.

BY WALTER P. BOWERS, M.D., CLINTON, MASS.

THE subject assigned me has, in many of its aspects, been considered many times in the past decade, either by itself or as a feature of the laws requiring that physicians report contagious diseases. I had supposed that about the last word had been said, but since the secretary asked for a consideration of this matter, there must be a definite reason.

First, perhaps the law and rules of the State Department of Health, are not understood by physicians, or if understood, are not obeyed, and second, it may be that the people are antagonistic either to the law itself or to the way in which it is applied.

The law is clear and definite, as shown in Section 50 of Chapter 480 of the Acts of 1907, where it says that: "If a physician knows that a person whom he is called to visit is infected with any one of several diseases named, or any other disease declared by the State Board of Health to be dangerous to the public health, . . . he shall immediately give notice thereof in writing over his own signature to the Selectmen or Board of Health of the town." A penalty of not less than \$50, nor more than \$100 is provided for refusal or neglect to comply with this law.

Section 49 of the same Act provides that a

householder is obliged in the same way to give notice of the same diseases, and is also subject to a penalty not exceeding \$100.

The State Board of Health has decreed that tuberculosis is a disease dangerous to the public health, and therefore under these sections of the law, both the physician and the householder are required to report cases of tuberculosis.

It is my impression that very little has been done to instruct householders about their duty in this matter, and that most of the effort exerted has been by boards of health, and that confined, to a large extent, to sending circulars of instruction, and cards to physicians, which can be filled out and forwarded.

I also had the impression that the reporting of cases of tuberculosis was done less faithfully than when the doctor is dealing with the contagious exanthemata or diphtheria, but also that there is a gradual improvement taking place as a result of the activities of state and local health authorities, and the publicity campaign carried on by anti-tuberculosis associations.

A series of articles in the *Cambridge Standard* under dates of the 12th and 14th insts., attempts to show that cases of tuberculosis are not reported, and under the heading of "The Doctor Who Does not Report Tuberculosis," puts the blame upon the physician.

If these cases are not reported, the blame should be put upon the doctor, for the laity has not generally been made to understand its responsibility, and the people naturally leave these matters to the physicians.

Dr. L. A. Jones, one of the District Health Officers, prepared a paper, read in 1913, which shows the facts to be almost identical with those claimed by the *Cambridge Standard*.

The doctors are put into four classes:

"1. All doctors do not know tuberculosis when they see it in its early stages. The fullest knowledge of the diagnosis and treatment of tuberculosis is of recent acquirement, and physicians who learned their art two or three decades ago, and have been so busied with practice as to be unable to keep up a progressive course of study, simply do not know what may be termed 'the fine points' of modern diagnostic science with reference to this disease. It is emphatically stated by the highest medical authorities that when the symptoms of the disease become sufficiently advanced for the physician of this type to recognize them, all hope is past for the patient. Not knowing the disease some doctors therefore cannot report it.

"2. Then there are physicians who believe that it is not wise to tell a patient when he has tuberculosis, or consumption. The medical profession is limiting more and more the scope of this practice of secrecy, but it still obtains, where much more harm than good is done by it. Consumption has hitherto been so hopeless that doctors have been silent because of the effect the lay notion of hopelessness may have on a patient. This, however, is seen to be a most

mistaken policy. It is an evasion which sooner or later is exposed, and thus confidence is irremediably destroyed.

"3. Some doctors simply refuse to report either to the authorities or to the patient's family the existence of consumption because of the stigma it is supposed to bring with it. They would shield the patient at the expense of the public.

"4. Other doctors do not tell the patient that he has tuberculosis because the patient is, in certain early stages, unlikely to believe him, to regard him as an alarmist, and to transfer his consultation to another physician. This sometimes leads some doctors to put off with remarks about 'a weak chest' or 'a run-down condition,' what is really a case of incipient tuberculosis needing prompt and strict attention in the proper way."

A secretary of a board of health told me today that a certain physician found that after promptly reporting cases no more patients of this class applied to him.

There is a great deal said nowadays about standardizing the various departments of medicine. We are urged to standardize our hospitals, to standardize our surgery, etc., etc., and it may be well for us to recognize some simple working formula in dealing with our patients who present symptoms indicative of early tuberculosis, for the purpose of making clear just what their symptoms indicate, and that a study of the case for a comparatively short time will decide the matter, and for their own good these patients should be willing to coöperate with the doctor in having the case reported while it is even in the suspicious stage. Therefore there may be a field for the activities of our organization in securing more and better coöperation on the part of the people, but we must first secure better coöperation by physicians.

There is in law the theory that every attorney is a part of the machinery designed to secure the administration of justice. There should also be in medicine a strict adherence to the analogous theory that every physician is a part of the health administration of the state, and although not in all instances a member of a board of health, his duty is just as broad and definite as that of the elected official. I fear that average medical practice is quite as apt to fall short of this conception as that some legal practice is perverted from the highest ethical standards.

Here in Massachusetts the law is plain, the rules of the State Department of Health are clear and definite, and every intelligent practitioner knows his duty.

Because of the natural alarm usually experienced by the patient and friends, and the prejudice aroused in having to be investigated and controlled by authorities, we must feel the greatest sympathy for those directly concerned, and should make all possible effort to relieve one already suffering mentally and physically, from unnecessary annoyance, and lead rather than

coerce a patient to coöperate with the authorities. But to the medical man the problem is simple, direct, and does not admit of elasticity. All doctors who do not loyally comply with the law should be made to do so, first, because it is a duty which one owes to the state, and, second, because of the advantages to the patient.

The duty to the state is to prevent disease, and the state is in the first instance dependent upon the practitioner to put into operation the proper machinery for the control and elimination of the danger.

In order to do this, all facts pertaining to the prevalence of the disease must be available, and to be of the greatest value must be known early. Where it is found that the mortality records exceed the morbidity records, there is a reasonable ground for criticism, for where people die of tuberculosis without having been reported, the disease has existed uncontrolled. Present knowledge, if put into operation, is undoubtedly sufficient greatly to reduce the economic loss from tuberculosis.

The great majority of people can be influenced to coöperate with any plan which promises better conditions if dealt with diplomatically, and it is possible that progress is hampered more by indifference and ignorance of some physicians than by the laity.

Sanatorium officials and other experts have supported the assertions made above and have told me that the doctor of average ability cannot or will not recognize tuberculosis in its early stages. If the average doctor does not, then most of the practitioners below this status surely will not.

Their failure to recognize the disease early is due either to inability to understand the problem involved or to the fact that some practitioners have not taken time to familiarize themselves with modern diagnostic methods, or devote sufficient time to each individual case. Sometimes the popular busy doctor is one of the offenders, and his methods may support the statement sometimes made that the doctor to be avoided is the one who may be popular, and hence overworked. If these contentions are sound, they constitute a seathing arraignment of the profession, and we should look for the remedy.

This remedy seems to lie in efforts to educate physicians already in practice and also in an education of the law makers who hitherto have declined to enact a good registration law; and constant effort should be made to lead the people to understand that there is danger in the incompetent practitioner of medicine, and uniformly good medical service can never be secured until the law requires that every registered physician shall be well trained.

Massachusetts has been one of the fields for the work of the medical pretender, and we are living under the shadow of that calamity which gave state license to all medical frauds who had been deluding the people for a period of three years or more, for all such were allowed by the

medical practice act to continue to fool part of the people all the time, and even now the state makes it possible for untrained men, who have a memory sufficiently active to repeat that which may be culled from quiz compends, to be registered.

Dr. Holmes, you know, regarded mere memory as the lowest intellectual attainment, and yet our system does not require that a man must be trained to use his eyes, ears, fingers or reasoning faculties, to become a practitioner. If he can write from memory a reasonably good book, he can sometimes secure registration. Even under this defective law many imperfectly trained men are rejected, but the board having this matter in charge is handicapped in not having the right to require that a man shall have been properly educated before securing the privilege to practice.

The state, for the protection of its citizens, should either amend this law, making it obligatory that applicants for registration should have had good training, or else it should provide the means for examinations which would be a sufficient test. Such examinations would have to last over a period of weeks to be of value, and are unnecessarily cumbersome.

This organization should be interested in medical legislation, and demand of the law makers that Massachusetts shall have at least a good average law. When such laws shall have been enacted, the usual natural process of death will gradually clear the state of the low grade doctor.

The remedies then, so far as doctors are concerned, consist in a better medical registration law, and an enforcement of the health regulations, and here we come to another matter which needs correction.

The law requiring reports of cases of tuberculosis is good. The administration of this law, not as it should be.

As a preliminary to the study of this subject I asked for information from boards of health and secured 109 replies. These replies show that in 29% of the reported cities and towns the law is not complied with, and in these 31 cities and towns the proportion of unreported cases runs from 12% to 100% of the cases known. Only three boards of health report prosecutions under the law.

This is an arraignment of the boards of health. In order to sustain my contention, let me give you their own testimony. I will only read a few reports. One questioned my authority to ask these questions, and I replied that I had no official authority, but that as a citizen of the state, asking information, I had intended no offense, and asked this official to come to this meeting. I hope he is here.

RECAPITULATION.

The state recognizes the importance of reporting cases of tuberculosis, and has made laws requiring this procedure.

The laity rarely comply with the law.
Physicians frequently do not comply with the law.

Twenty-nine per cent. of the boards of health do not enforce this law.

REMEDIES.

Educate the people.
Adopt a better medical practice act.
Make the doctors comply with the law.
Make boards of health enforce the law.

VII.

TUBERCULOSIS ASSOCIATIONS AS HEALTH EDUCATORS.

By MICHAEL M. DAVIS, JR., PH.D., BOSTON.

Director of the Boston Dispensary.

TEN years ago the campaign against tuberculosis was a dream in the minds of a few enthusiasts, who, in 1905, organized the national association for the study and prevention of this disease. Today the campaign is a great national movement with associations in every state and many cities and, counting private and public funds together, it is spending \$20,000,000 a year.

The movement has developed hospitals, sanatoria, dispensaries and visiting nursing; but above all, a great educational campaign. Twenty million dollars are not taken from taxes or from philanthropic purses unless tax payers and givers believe that the results justify the expenditure. The belief that expenditures to relieve and prevent tuberculosis are worth while has been developed in the public mind through a persistent process of education. Last autumn 44,000,000 Red Cross seals were sold in the United States, nearly 2,000,000 in Massachusetts, and every Red Cross seal is a teacher. The anti-tuberculosis campaign has been first and last an educational campaign, as all "reform movements" fundamentally are.

With such remarkable results as the ten years' fight against tuberculosis has shown, the time has gone by when tuberculosis associations need devote much attention to explaining the importance of preventing this disease. The general campaign of education has largely completed itself and the public now needs education on specific points. The tuberculosis germ has proved itself a money-raiser. The time has come when, under the slogan of preventing tuberculosis, and with the leverage and the money which the anti-tuberculosis campaign furnishes, a broad health campaign must be waged, while at the same time attention must be devoted to the education of the public on specific questions of importance, for the reduction of waste or inefficiency in present anti-tuberculosis work.

The very success of the anti-tuberculosis campaign has brought with it two dangers. First,

that of over-specialization, a danger which creates, as it were, a vested interest in preventing tuberculosis, and fails to see its intimate relationships with other phases of militant public health work. The second danger is the popular fear of tuberculosis, which has been so developed as a by-product of the educational campaign that it acts in many ways as a handicap upon existing work and upon further progress. Anti-tuberculosis associations in their capacity as educators must devote themselves to informing the public that while it is well to fear tuberculosis, it is not well to fear it in the wrong way.* The dread of the disease should be based on information as to how the infection is most likely to be carried. They must understand that the way in which infection is usually carried renders a tuberculosis hospital harmless, either to life (or property values) in its vicinity; but that, on the other hand, an active consumptive in the midst of his home and family is dangerous to wife, neighbors, and above all, to the children.

Tuberculosis associations have issued millions of "don't cards." A card with one half headed "When to Fear Tuberculosis" and the other half "When not to Fear Tuberculosis" might be worth considering. Fear is a lever if it is intelligent; but a clog when it merely represents ignorance or half-knowledge.

As health educators, anti-tuberculosis associations must teach the public to stop the waste of money and effort which arises from the discharge of sanatorium patients without adequate supervision after they leave the institution.

The reports of the state sanatorium trustees have emphasized the value of the worker now engaged in this service,—a value not only to certain individual patients, but in stimulating greater activity and effectiveness of local bodies in supervising tuberculosis. The public must be educated to understand that it is not economy to see this work stop with the provision of only one worker; that further provision, correlating the sanatoria with local communities will much more than pay their cost; for the annual expense of the state sanatoria is over \$600,000.

As health educators, tuberculosis associations must educate both the doctors and the public towards the early diagnosis of the disease. It is already well recognized that this should be among the features of the campaign; but how make it a more effective feature? It seems as if the time had come when the most effective way to demand early diagnosis of tuberculosis is to call for frequent, periodical, general medical examination by skilled physicians. People may fear to go to a clinic or office which bears the label of tuberculosis; but they have no ground to dread a general medical examination. It is particularly fitting that we should use the public interest in

* Such studies as that of Dr. H. B. Lampson (U. S. Public Health Reports, January 8, 1915) supply excellent educational material. The general public should know that "ordinary exposure such as everyone encounters" was found in Dr. Lampson's studies to bring only 8% of infection, while intimate exposure brought 79%. Such concrete studies when made known to the lay public carry conviction as to the manner in which the infection is spread; while general statements glide too easily in and out of mind.

tuberculosis as a lever in the broader campaign for better medical supervision of all persons, for no disease is more dependent upon general living conditions than is tuberculosis.

As health educators, finally, anti-tuberculosis associations must strive to stop the waste arising from the development of more and more specialties. I have spoken of over-specialization as one of the dangers to which the tuberculosis campaign has led. A string of "public health movements" has followed in the wake of the anti-tuberculosis campaign. There are now societies to prevent infant mortality; to promote better obstetrics and establish pre-natal clinics; societies for school hygiene, for mental hygiene, etc. Each of these agencies is pushing forward special health needs, is advancing a special technique, and is putting doctors, clinics and visiting nurses into the field. Even in smaller communities often two or three, or perhaps four, of these special health interests will be actively engaged in field work. The anti-tuberculosis association may well strive to pool the health interests of a locality and coordinate the special clinics or nurses in one cooperative group, whether they are maintained by a city or by private agencies. Clinics may be combined in one building, the work of different nurses may be coordinated or generalized; and this without the impairment of the integrity of the different organizations supporting the branches of the work. Such pooling of health interests will mean financial economy and gain to public health. Inasmuch as no movement is more dependent for its success on the general advancement of public hygiene than is the anti-tuberculosis movement, none will profit more by this coordination of special activities.

The time has come when tuberculosis associations must be health educators, because this is the more effective way to be tuberculosis educators. The anti-tuberculosis campaign must be a public health campaign, if it is to be most effective. Let public health be on the banner borne on the front of the ear, while the public interest in preventing tuberculosis, already aroused, will furnish the gasoline.

VIII.

THE RESPONSIBILITY AND OPPORTUNITY OF THE TEACHER IN PREVENTING TUBERCULOSIS.

By THOMAS F. HARRINGTON, M.D., BOSTON.

Director of School Hygiene, Boston.

MUCH of the apparent disagreement among authorities relative to the prevalence of tuberculosis among children is due to the fact that a distinction is not made between a tuberculous infection and a tuberculous disease. It is now admitted generally that all persons are infected with tuberculosis at some period of life. The great majority recover without ever knowing

that they had been infected. In childhood, it is very difficult to detect tuberculosis either by physical examinations or by recognized tests. Reliable data at hand demonstrate that relatively few infected children go on into the tuberculosis state. All infected in the first year or two of life die. Only ten per cent. of all deaths from tuberculosis occur during the ages of five to twenty years, inclusive. Even in families of the tuberculous, the infection of the exposed children is hard to demonstrate. In Boston, there are 7000 cases of positive tuberculosis on record at the office of the Health Department; these people live in 1340 families in which there are 2131 children of school age. A recent study of these children, by which the school nurses secured a report from the family physician or from a hospital clinic, showed that only 304 of the children had tuberculosis in a form that could be diagnosed. A later study of 196 children diagnosed as positively tuberculous confirmed this diagnosis in only eleven cases. Fourteen children of the group were diagnosed as doubtful; forty were deferred for subsequent observation, while 92 children of the group were returned to school as negative cases. A study of over 90,000 pupils in our elementary grades shows that five per cent. of the children were anemic, glandular, or under-sized. In other words, they were physically below par to a degree requiring preventive measures if they were to be saved from genuine tuberculosis. All reliable evidence today demonstrates that the education of the public in the cultivation of hygienic habits of living is the most effective means of combating tuberculosis. Obviously this leads us at once to the classroom. Here are grouped by compulsion, for a long period of the formative age of children, about one-fifth of the population. The opportunity to establish right habits of living is far greater in the school than at any other period or place. This the state of Massachusetts recognized early in the enactment into law that "schools shall give instruction in physiology and hygiene," and further that "in each of the subjects of physiology and hygiene, special instruction as to tuberculosis and its prevention shall be taught as a regular branch of study to all pupils in all schools supported wholly or partly by public money." Other subjects may be taught, e.g. algebra, geometry, language, natural science, kindergarten training, manual training, etc., if the school committee thinks such teaching expedient. Furthermore, the statute provides that every city and town of 10,000 or more inhabitants shall maintain a school in which the subjects of physiology and hygiene shall be taught, and towns which do not maintain a school as required by the statute shall not be entitled to its portion of the appropriation allowed from the "Massachusetts school fund." Nor does the responsibility of the school end here. A further act is mandatory in its provision that "the school committee of each city and town shall appoint one or more school

physicians, who shall make a prompt examination and diagnosis of all children referred to him, and such further examination of teachers, janitors, and school buildings as in his opinion the protection of the health of the pupils may require." Also that every child in the public schools shall be separately and carefully tested and examined at least once in every school year; and further, the school committee is required to keep a physical record of each child and to give notice to the parent or guardian concerning the defects or disability requiring treatment. The statute also places upon the State Board of Education and the State Board of Health the responsibility for carrying out the provisions of the act, including the giving of adequate instruction on these subjects to the pupils in the normal schools. Later legislation requires that all children under sixteen years of age, seeking a working certificate, shall be in good health, sufficient to undertake the work for which the application is made. We might go even further and point out the dangerous trades and occupations which minors, eighteen years of age and less, cannot enter; these trades and occupations require that teacher and school physician shall have some knowledge of the processes involved if they are to act as guides to the pupils entering vocational life. The limited time at my disposal necessitates the restriction of the whole problem to two points only, namely, first, in what manner is physiology and hygiene teaching being carried out; and secondly, what can this state anti-tuberculosis association do to aid in efforts to meet the requirements of the statutes on these subjects. Let us divide the problem into:—

1. The teaching of physiology and hygiene.
2. Medical inspection.

THE TEACHING OF PHYSIOLOGY AND HYGIENE.

Data collected recently from most of the cities and from many of the towns justify only one conclusion, namely, that no subject in the curriculum is so neglected or so inadequately taught as the subject of physiology and hygiene. Many superintendents write candidly that nothing is being done in their communities to carry out this law. Others present a course of study in which less time is allotted weekly to this subject than to any other subject in the daily program. In only a few cities is any special instruction given in the prevention of tuberculosis. There is little or no definite policy carried out, other than in notable exceptions, covering classroom temperature and open windows. Only two courses of study show any correlation between such habits as cleanliness, good teeth, food, sleep, fresh air and sunshine, and the daily home life and school life of the child. The opinion of the superintendents seems to be unanimous that the cause for this state of affairs lies in the lack of preparation of the teacher for the responsibility placed upon her by the statute. In the normal school, where any attention is given to this spe-

cial subject, the course of study is so scientific and so overloaded with anatomy often that it defeats its own object,—namely, to give the teacher-pupil a preparation in methods of teaching the subject in the grades.

The prevention of tuberculosis is not given serious consideration in many of the normal schools.

MEDICAL INSPECTION.

Here the situation is akin to that of physiology and hygiene teaching—namely, inadequate preparation for the work and the lack of a just appreciation of the responsibility involved. Many physicians here and there are making great personal sacrifices to do this work well. On paper, many cities have a very attractive organization; too many communities fail to recognize the tremendous power of health supervision in raising the physical and mental standard of the group as well as of the individual. In only a few cities and towns is there any team work between the health and the educational departments. Little or no medical inspection can be effective unless the teacher is prepared to select the children needing medical care. Normal schools and medical schools are not giving their pupils special preparation. Medical inspection without a "follow up" by school nurses is in the vast majority of cases (more than 90%) a waste of time and statistical gathering only. No remedial or corrective results follow such an inspection. On the other hand, there is a decided trend to rely upon the teacher and nurse combination without the guidance of a school physician. No school principal nor superintendent should take the responsibility of this problem unaided by some medical authority. In summing up, therefore, it can be said that an organization such as this association can do a great good in cities and towns, first, by urging school and health authorities to get together to carry out the statutes quoted above; second, by requesting school authorities to legislate that windows in class-rooms be kept open and that room temperature be kept between 60 and 65° F; third, by establishing open-air classes for the debilitated children who are not frankly tuberculous; fourth, by providing literature on tuberculosis prevention for distribution in the schools; fifth, by demanding that teachers and physicians be prepared, in normal schools and in medical schools, for this special work.

IX.

MEDICAL INSPECTION OF SCHOOL CHILDREN.

By FRANCIS LEE DUNHAM, M.D., BROOKLINE, MASS.

INVESTIGATIONS in the department of school hygiene comprehend as many factors of social as of medical or educational importance. Consequently an intimate coöperation between the

school and existing social agencies should be encouraged. The logical approach to the problems of the tuberculous child is through intelligently directed school health supervision. It is toward this specific aspect of the subject that the following suggestions are directed:—

The difficulty encountered in changing long established reactions in adults is generally recognized. It is next to impossible to change an unintelligent parental attitude toward oral hygiene, adequate bathing, proper ventilation, sex hygiene, and other refinements tending toward physical and mental efficiency. Yet intelligent direction in the schoolroom shows definite, practical results. As an example, contrast the daily use of the tooth brush by 98% of the children in a school with poor environment, following six months' instruction, with less than 40% at the opening of the school year. The result is a permanent improvement in the personalities of the children themselves, and is the most logical approach to an intelligent parenthood.

The school child as a potential focus for tuberculous infection cannot receive too insistent attention. One is constantly discovering adolescent children who bear the scars of early infection. The number of anaemic, malnourished, neurasthenic children, suffering from a tuberculo-toxemia of unrecognized causation is distinctly correlated with the pallid children of pent-up schoolrooms. The scant recognition given to a thorough examination of the 700,000 school children of Massachusetts is mirrored in the inadequate returns made to the State Board of Health respecting the prevalence of the disease.

Although adequate ventilation is recognized as the most potent factor toward securing efficiency from both mind and body, schoolrooms are allowed to be sealed during the winter months. The employment of teachers and janitors of deficient physical health and hygienic training is largely responsible for this unfortunate state of affairs. The acute, infectious cold, which is the basis of much later infection, could be rendered a far less potent cause of disorganization if all schoolrooms were overflushed with open air night and day. I have kept a winter schoolroom at a temperature of 60° with no complaint of discomfort from pupils and with increased mental efficiency. However, such a condition presupposes a healthy teacher and an intelligent exercise of judgment as to change of posture and the use of overgarments, if asked for.

The tendency to regard artificial fumigation as an adequate bactericidal measure in inhibiting contagion is a highly fallacious one. The fumigating plant at the disposal of the ordinary town board of health is perfectly useless save for moral effect. This may be easily proven by any one caring to take the requisite experimental trouble. Desks, seats and floors, thoroughly washed with hot, alkaline, antiseptic solutions and the abolition of dust-collecting oils

will render virulent, incubating chambers, sanitary classrooms.

The development of a constructive, school hygiene through the employment of specially trained persons to act as assistants to the health inspector will greatly assist the present unsatisfactory service. Such assistants should be thoroughly trained in the technic of hospital nursing, social service, and school hygiene; they should be carefully chosen and adequately paid.

To summarize I would suggest:—

1. Individual instruction in school hygiene.
2. An increased professional activity.
3. Insistence upon open windows.
4. The development of a constructive policy toward school hygiene assistants.

X.

TUBERCULOSIS WORK IN THIS STATE.

By AMY F. ACTON, BOSTON.

Chief Inspector of Incorporated Charities, State Board of Charity of Massachusetts.

You may be interested, at the outset, to learn how the work of the State Board of Charity fits into the supervision of private charities, in which category are included the anti-tuberculosis organizations.

The statutes covering the subject are found in acts of the legislature which severally provide that before issuing a charter for charitable purposes, the secretary of the Commonwealth shall refer the matter for investigation to the State Board of Charity¹; that after incorporation, the board shall annually visit and inspect the work of such organizations as consent to or request such inspection²; and that such charities shall report annually to said board.³

Under the act providing for inspection, the various incorporated anti-tuberculosis associations have been visited from time to time and information gathered as to their policies and methods.

NUMBER OF ANTI-TUBERCULOSIS SOCIETIES IN STATE.

In the 353 cities and towns in this Commonwealth, there are 34 organizations for anti-tuberculosis work which are more or less active. Eleven of these are incorporated anti-tuberculosis societies and six are committees affiliated with other incorporated agencies, such as district nursing societies,—a total of 17 agencies coming within the inspection law.

Twenty-five out of the total 34 private agencies are situated in 24 cities and towns having more than 10,000 population,⁴ and there are 30 communities with more than 10,000 inhabitants in which there is no private agency for anti-tuberculosis work. Eleven of those thus left uncovered have more than 25,000 population. There is, therefore, work awaiting anti-tuberculosis agencies yet unborn.

STANDARDS.

In estimating the value of the work of the various anti-tuberculosis societies, we must first consider the standards by which to measure that work.

Failure of these agencies in the past to standardize and put the right valuation upon their various activities is undoubtedly responsible in large measure for the lack of uniformity in their aims and methods and the failure of several of them to carry on effective work.

It appears to be the well settled opinion of those who have studied the situation that the private anti-tuberculosis organizations should, so far as possible, confine themselves to the education of their communities in the best methods of preventing the inception and spread of the disease; that is to say, it is their part to do the educational work. If for any reason they deem it wise to take on activities that are outside the scope of educational work, opinion seems to indicate that they should do so with the intention of demonstrating the need of such activities and of transferring them to other agencies as soon as practicable.

The reasons for urging the anti-tuberculosis societies thus to confine themselves to the education of the public are: (1) the great need of such work and the fact that only private funds can be used for such a purpose; and (2) that the task of seeking out and caring for those afflicted with the disease, and the cost of the work, are of such magnitude that private societies cannot handle it, while the tax payers have assumed it as their rightful burden. As a part of the state policy for caring for the individual, we have sanatoria for curable cases, and state laws providing for the establishment of municipal hospitals in cities; municipal dispensaries in cities and towns with a population of more than 10,000; the medical examination of school children; the instruction of school children in avoiding the disease; and provision for the reporting by physicians and householders to the local boards of health of cases of tuberculosis.

With such provision, and adequate laws requiring the municipalities to assume their obligations, it appears to be the province of the private societies to encourage and stimulate their communities to do the work assigned to them rather than to relieve them of it.

Let us see what the various anti-tuberculosis societies are doing to assist in the development of this state policy.

First. Are they endeavoring to awaken public interest in regard to the law requiring the cities of this Commonwealth to maintain tuberculosis hospitals?

In 16 of the 35 cities and in 3 towns,²⁰ there are 21 such institutions which have been approved by the trustees of the hospitals for consumptives. In another city, a hospital is being built. Two of this number are maintained by anti-tuberculosis societies. During their last

fiscal year, they cared for a total of 243 persons, and their expenditures were \$38,238. These two societies are doing almost nothing along strictly educational lines, and instead are assuming the tasks which belong to their own municipalities.

Of the 19 cities which have not yet complied with the hospital law (8 of them having over 32,000 population), 7 had anti-tuberculosis societies which died of inanition; while 8 have existing societies. Of these latter, 3 do nothing along educational lines and 4 do little. The other, which is quite active, has not urged the erection of a hospital by the city as there is reason to think that a private individual will assist in its establishment. There are, therefore, opportunities for anti-tuberculosis societies to assist in getting municipal hospitals in these cities by adopting active educational methods to arouse public opinion.

Second. Are the private anti-tuberculosis agencies endeavoring to awaken interest in the law requiring cities and towns with more than 10,000 population to establish tuberculosis dispensaries?

Of the 54 cities and towns coming within this law, 31 have not complied with it. (One of these cities has just provided for a dispensary in its budget.) Seven of these 31 cities have more than 32,000 population, and 8 of them have existing anti-tuberculosis organizations. Only one is very active along educational lines. Fifteen of the 31 localities have never had anti-tuberculosis organizations, while 8 have lost them by death.

Of the 23 existing dispensaries, a number are below the minimum standard set by the State Department of Health, in respect to having no evening hour, no medical staff, etc.; 8 are carried on by private anti-tuberculosis agencies, 2 of them in cities already provided with municipal dispensaries. One society is now endeavoring to get the Board of Health to take over the clinic which it has conducted for several years.

Third. Are the anti-tuberculosis societies endeavoring to awaken public interest in the enforcement of the law requiring medical examination of school children, which is required in every city and town in the Commonwealth?

Some of the societies believe that this work is not well done in their communities. No statistics on this point have been gathered by the State Board of Education since June, 1913. At that time, replies from the cities and towns indicated that in a number of localities no physician had been appointed, that where a physician had been appointed not all of the children were examined, and that in many instances the examination was largely confined to the eyes, nose and throat. With few exceptions, the unsatisfactory replies were from small communities. Four of these places have anti-tuberculosis agencies at present. One of the most serious problems in this connection is the entire lack of medical inspection in many of the children's institutions

whose inmates do not attend the public schools. An instance recently came to my attention where three such children, a boy and his two sisters, were found to be affected, two of them being in an advanced stage of the disease when they were removed from the institution. This question of bringing about an adequate medical examination of public school children and other children of school age, and also of instructing them in the cause and prevention of tuberculosis, presents many opportunities for educational work on the part of these societies.

Fourth. Are the societies striving to awaken public interest in the enforcement of the statute requiring cases of tuberculosis to be reported to the local boards of health? Seven organizations believe that the law is not well obeyed, and yet six of these do but little work on educational lines. This measure is so important and the failure to enforce it so often indicates an inactive board of health, that the anti-tuberculosis societies can well afford to undertake an active campaign to interest the public in this direction.

Turning from the state's formal program for controlling tuberculosis, and the part which the anti-tuberculosis societies are taking to educate the public to carry it out, let us consider what work remains to be done by private funds and what agencies are doing it.

1. Instructive and home nursing in tubercular cases:—

Fifteen anti-tuberculosis agencies, some of them in the larger industrial cities, employ nurses to instruct patients in their homes. In some of the cities where this is done the local boards of health already employ one or more nurses for this purpose, so that in these instances the societies supplement what they believe to be inadequate service on the part of the municipality. This visitation and instruction of individual patients is conceded by most of those who have carefully considered the matter to be the duty of the local boards of health. If this view is correct, the societies should not regard their instructive work as a permanent feature, and local boards of health should be urged to take it over as soon as practicable.

Several societies which formerly employed nurses for instructive nursing have adopted this view and have since devoted all their energy to work on educational lines. One newly organized agency plans to employ a nurse for a short time to make an investigation as to whether the community needs a dispensary. This is in accord with the theory that the workers in these agencies should devote themselves to gathering information as to the needs of the community and disseminating such information.

It is even more generally conceded that the anti-tuberculosis societies should not attempt to care for bedridden patients. This is not generally done, though in two cities the instructive nurses are inclined to do more or less home nursing of tubercular patients, instead of turning them over to the local nursing associations,

which are willing and able to care for them. One anti-tuberculosis agency which does not co-operate well with the visiting nursing association in this regard devotes itself wholly to individual work with patients and does nothing on educational lines.

2. Providing tubercular patients with material relief.

At least seven anti-tuberculosis agencies undertake to provide material relief, chiefly in the form of milk, eggs and other food suitable for tubercular patients. In five of their communities there exist societies for organizing charity. Three of these latter agencies are well equipped to handle all relief problems in families where tuberculosis or other sickness or misfortune is the cause of poverty. When an anti-tuberculosis society furnishes relief in a community which supports a well organized associated charities or a relief society, such a step involves not only duplication of work but a departure from the best recognized standards set for private societies in the field of tuberculosis prevention.

It is easy to understand that local conditions or lack of resources in the community have made it necessary for agencies in some instances to maintain a hospital or a dispensary, give instruction in the homes of patients, furnish material relief and find suitable work for patients in whom the disease has been arrested. The important thing is that they should regard these as temporary activities and endeavor to turn them over as soon as possible to some appropriate agency. Only by so doing will they be in a position to enter upon an active campaign of education.

As I conceive it, the work of the private society is to gather information touching the cause and prevention of tuberculosis by studies and other means; to disseminate it as widely as possible; and to interest the public to support necessary legislation.

The societies which are doing the most active educational work employ popular lectures, moving picture films, exhibits in schools, shop windows, etc., leaflets in different languages, popular articles in the press, competitive essays by school children, and all other educational methods which human ingenuity can devise. Ideas presented thus reach a vast number of persons at a stage where suggestions for avoiding the disease may be helpful and before control becomes necessary. This, from the viewpoint of state inspection, should be the work of the private society which enlists in the fight against tuberculosis.

Medical Progress.

A REVIEW OF SOME OF THE RECENT LITERATURE ON PERICECAL BANDS AND ADHESIONS.

By WILLIAM JASON MIXTER, M.D., BOSTON.

IT is safe to say that there are at least three types of adhesions: (1) excessive embryonal fusions, (2) inflammatory and traumatic processes, (3) mixed. During the past two years we find an increasing number of writers who lean toward the embryonic origin of these structures, some of whom are on record in the past as believing them to be largely inflammatory. It seems certain that during fetal life there is a mysterious sort of adhesive peritonitis with a selective action on certain folds of the peritoneum, which accounts for the fixed portions of the intestinal tract (Bryant¹). Just how this process takes place is not known, but if one thinks of the contents of the peritoneum becoming more or less adhesive during the evolution of the colon in fetal life, all the findings would be explained. The whole mesentery of the large intestine becomes adherent, each portion to its own chosen structure except that of the sigmoid. This is a very extensive process and it is easy to see that comparatively slight variations would lead to important anatomical changes. Suppose the process is very active on the ascending colon, Jackson's veil is the result from the dragging over the intestine, by its adhesive property, of a fold of peritoneum, much as one pulls up a blanket on a cold night. If the process runs up on to the mesentery of the lower ileum, the intestine rolls up in its own mesentery and we get a Lane kink. Naturally, different writers show minor differences of opinion, but this seems to be the fundamental idea as expressed by Mayo,² Eastman,³ Summers,⁴ Fallon⁵ and others. The possibilities are endless, and it is easy to see that the resulting abnormalities would at least be very similar to the results of peritoneal infection. It is probable that pericecal membranes are present in at least 15% of children (Abrecht⁶), while Eisendrath and Schnoor⁷ and Fallon⁸ claim that Jackson's veil is a fold which is always present to a greater or lesser extent. They say that the Jonnesco and the Jackson veils are synonymous. The structure is a reduplication or fold of peritoneum constantly found during fetal and post-natal life and varies greatly in vascularity. The upper border is at the hepatic flexure and the lower is usually 1 to 1½ inches above the lower border of the cecum, although in some cases they found it covering the whole cecum and part of the appendix.

Another embryonic process which it is necessary to note in this connection, although it involves the cecum only indirectly, is the Lane kink. The mechanism of this abnormality is much clearer and can be explained as a rolling up of

the terminal ileum in its own mesentery. There may be variations, but this is the fundamental process. Campbell⁹ found the condition present to a greater or less extent in 18% of a series of cadavers.

To take up next the adhesions of infectious or traumatic origin—they are so diverse both as to cause and position that it is only necessary to mention the appendix as the commonest single cause and that their varieties may be endless. A good example of this process is the deformity of the lower ileum caused by appendicitis when that organ lies against its mesentery. The resultant scarring of the peritoneum may draw the terminal ileum downward in such fashion that it almost exactly simulates a Lane kink of embryonic origin. The same may also be true of tubal inflammations. Eastman³ partly differentiates such processes from the congenital type by absence of blood vessels. The main difference is the fact that they are usually, but not always, firm, white, localized bands of bloodless connective tissue. They seldom show any orderly arrangement as the congenital veils do, and may catch any loop of bowel. They are often fine string-like processes. If the omentum is involved, it usually springs straight across to the site of inflammation about the cecum without any intermediate process between it and the ascending colon, as is the case in the congenital type.

It is easy to see that the embryonic process results in strong points of support for the colon throughout nearly its whole extent. If these supports are unduly narrowed at any point or if they draw across the gut, they will cause angulation or constriction of its lumen with resulting stasis after the musculature loses its tone. If there is unusual overloading of the intestinal tract due to loss of habit of defecation or any other cause, the same angulation will occur at points of support which under a lighter load would act properly. Under these circumstances they become danger points, and by causing increasing stasis with its resulting putrefaction give rise to mild grades of colitis and pericolicitis.

This brings us to the commonest type of case seen at operation,—the mixed type. In this, the congenital type acts as a forerunner to the chronic adhesive process of adult life with its persistent low grade infection and its ever-increasing obstruction and stasis, thus forming a vicious circle. Associated with this is the increasing density of the embryonic structures due to the tugging of prolapsing organs or a mild degree of inflammation, as pointed out by Pilcher.⁹ When such cases come to operation, it is very difficult to tell where the embryonic process ends and the inflammatory one begins. Luckily this makes comparatively little difference surgically.

We now come to the mobile cecum of Wilms. Here again developmental conditions play a very important rôle. If there is a meso-cecum and ascending meso-colon, the

cecum, being a comparatively heavy blind pouch supported against the abdominal wall in all the animals which do not stand erect, sags down into the pelvis, and the more it sags the more difficulty it has in emptying itself. Hausmann¹⁰ recognized three types: (1) due to a long common mesentery, (2) due to sliding or flaccid slack retrocecal tissue, and (3) due to long mesentery of the ascending colon and hepatic flexure. Case¹¹ and others, while not denying the presence of this condition, say it is not nearly so important as the fixed cecum. Connell¹² found it present in 11 out of 19 operative cases. It is probable that it may also be due to a dilatation and elongation of an originally normal organ by means of constricting bands involving the ascending colon, with resultant stasis. The general feeling among American surgeons seems to be that dilatation of the cecum is of far greater importance than its mobility. Cannon¹³ and others have proved that the cecum is a reservoir which is intended to hold its contents for a considerable time, and if we look to the lower animals we find that those vegetable feeders with enormous ceca have very much less constipation than the carnivora in whom it is rudimentary. That this is due to the type of diet undoubtedly is true, at least in part.

That excessively redundant ceca may cause no trouble was proven in one of my own cases two years ago. The patient, a woman, had an enormous left inguinal hernia. Even when she was lying down, the lower end of the sac was level with the upper edge of the patella. At operation, the cecum was found firmly adherent at the very bottom of the sac, and yet this patient had never been troubled greatly with constipation.

Our last anatomical consideration is the ileocecal valve. Case,¹⁴ Dodd,¹⁵ Baker¹⁶ and others have shown that it is frequently incompetent and that this incompetence is usually associated with stasis in the lower ileum, giving rise to a more or less well defined symptom complex. Case¹⁴ reports it to be present in 17% of all cases. This valve is of great importance in preventing the regurgitation of the cecal contents, which are very rich in bacteria, into the ileum, where bacteria are much less numerous. Naturally this results in putrefaction taking place in an organ which is not suited to it, with resulting absorption of decomposition products. When we look into this matter we find that there is considerable unanimity of opinion as to the fact, but rather less so as to the cause. First on the list comes congenital deformity of the valve itself. This is probably not so common as dilatation of the valve with relative insufficiency due to dilatation of the cecum from obstruction of the colon (Case¹¹). Third comes deformity of the valve from inflammatory conditions, such as adherent appendix, etc., and fourth, pulling on the ileum, withdrawing it from its partial invagination into the cecum and making it incompetent. Thus we have a definite deformity of the valve, usually secondary to some other pro-

cess, but which as a rule is not remedied by the removal of the original cause.

Absolute diagnosis of these varying conditions is difficult and varies somewhat with different authors. I shall not take it up in this paper more than to say that there is a fairly definite symptom complex associated with ileal stasis and that this is the dominating feature. Positive, differential diagnosis can be made only by means of the x-ray, and even that is not always certain.

TREATMENT.

Naturally we find that the treatment recommended by different authors is very variable, but it is possible to reconcile many of these variations when we recognize the underlying condition which each man is proposing to treat. It is absolutely necessary to remember that in this condition each case must be treated according to the findings, and that no hard and fast procedure can ever be successful in all cases. Even where the underlying cause is the same, the resulting pathological processes may be very variable and demand very different treatment. Many cases with quite severe deformities show little or nothing in the way of symptoms, while others, which have marked symptoms, at operation will show an almost normal abdomen.

I cannot hope to cover all the indications for the different operations proposed, but can simply discuss a few of the best known and those which seem to me the most efficient. Medical treatment is often successful in removing symptoms, temporarily at least. Baker¹⁶ advised cutting down the proteids and increasing the carbohydrates. At the same time, green vegetables and fats should be taken freely to increase the bulk and lubricate the stools. As a rule it is necessary to use agar agar and Russian oil and sometimes some form of laxative. The stools should be bulky and evacuation should be thrice daily for a time at least. Bastedo¹⁷ adds to this, as a very important point, the formation of a good habit of defecation. Whipple¹⁸ advocates the use of lactic acid bacilli either by mouth or in the form of enemas.

In the absence of signs or symptoms pointing to some definite lesion, such as Lane's kink, definite obstructing bands, appendicitis, etc., it is probably best to try out medical treatment thoroughly before resorting to operation. We should remember that these people probably have a rather increased tendency to adhesion formation and that any laparotomy, no matter how carefully done, is almost sure to be followed by some adhesions. This fact probably explains, in part at least, the unsatisfactory result in those cases which Price¹⁹ has so aptly termed surgical junk.

Lane may well be called the originator of surgical intervention in this condition. His work is so well known that it is not essential to go into its details here. The three operations for which

he is justly famous are: (1) reduction of Lane's kink, (2) ileo-sigmoidostomy, (3) colectomy. The first of these needs no discussion other than to say that it has been somewhat modified by different operators, notably Coffey,²⁰ who plicates the mesentery on the side away from the kink in order that it may not recur. Ileo-sigmoidostomy has been variously modified. Morris²¹ uses a sharp-bladed crushing clamp inserted through the anus by an assistant, and passed through the walls of sigmoid and ileum by the surgeon. This is left in place two to four days. If safe and efficient, it must indeed be a very rapid method. Montprofit²² sutures both proximal and distal ends of the cut ileum into the sigmoid, the idea being to give better drainage. Dr. Samuel J. Mixter, in a number of cases has sutured cecum to sigmoid or transverse colon to save the ileo-cecal valve, and more recently Eastman²³ has advocated anastomosis of the lowest point of the cecum to the top of the rectum by means of a large Murphy button. As we have seen, it is of great advantage to preserve the ileo-cecal valve; so I should say, if the technical difficulties of Eastman's operation are not too great, that it was the best, as it also completely drains the cecum, which is prone to fill with fecal matter after ileo-sigmoidostomy. This question of backing up in the cecum is very interesting and is due to antiperistaltic waves, which apparently normally occur in the ascending colon in order that the cecal contents may not advance too rapidly.

In regard to colectomy, there have been few changes in technique since Lane described the operation. Naturally any improvement in the technique of the short-circuiting operation can and should be carried out in the other. Lardennois²⁴ has added one point, namely, that the transverse colon is easily dissected away from the back of the omentum by following its line of fusion. In this way, the omentum and its complete blood supply are saved.

The other modifications of the Lane operation are along the line of conservation, in that only a portion of the large intestine is removed.

Reder²⁵ resects the ascending colon and cecum, and then after doing a lateral anastomosis, ileum to colon, brings the blind end of the ileum out through the abdominal wall, thus leaving a vent which heals within three or four weeks.

Kellogg²⁶ has suggested the formation of an artificial valve where the end-to-side anastomosis is done. Mayo believes colectomy to be seldom necessary, as do Connell,¹² Lardennois,²⁴ Sorrel and others. These writers favor the careful dissection of the constricting bands with plastic repair of denuded areas, and also at times fixation of the intestine to the abdominal wall.

Oppel²⁷ has gone into this matter of reversed peristalsis, particularly after anastomosis, carefully. His conclusions may be epitomized as follows: Never leave a blind pouch without a fistulous opening and if possible never give the fecal stream a chance to go round a loop and

back to the same place. Both of these will result in symptoms of stasis.

Fixation of cecum mobile is advised by Wilms, Hausmann,¹⁰ and Duval.²⁸ The latter splits the peritoneum over the tendon of the psoas parvus and sutures the longitudinal band of the cecum to it. If, as we suppose, dilatation of the cecum is of greater importance than cecum mobile, these operations are to be used only in a small number of cases.

Repair of the ileo-cecal valve by means of several sutures placed in the sero-muscular coats constricting the opening and causing a slight intussusception, has been advised by Kellogg²⁶ and his views are confirmed by Case.¹⁴ This would seem to be a rational procedure in all cases where the ileo-cecal valve was incompetent. Martin,³⁰ on the other hand, claims that stasis is sometimes due to sphincterismus, and that if this is the case the muscle should be cut, permitting the valve to become more or less incompetent. This at first sight does not appear as rational a surgical procedure, but no decision can be reached until more cases have been done by both methods. Most recent authors agree that restricting bands should be severed and the intestine restored as nearly as possible to its original form whenever this seems to give probability of relief, rather than to do a short-circuiting operation or a colectomy. Emphasis should also be laid on various points of technique, such as little handling, plastic repair of peritoneum wherever possible, complete hemostasis and the elimination of dry gauze from the abdomen. It is a question whether oil introduced at operation does any good. Some authors say it does harm.

It seems to me, on thinking over quite a large number of cases seen as assistant and a small series as operator, that adhesions involving the large intestine are far more prone to recur than those involving the small, and that the dividing of bands causing constriction and angulation, is more important than fixation, and that short circuiting operations and colectomies are of greatest value where there has been a marked hypertrophic process in the large intestine, associated with the adhesion formation.

CONCLUSIONS.

The most important thing in the treatment of these conditions is that each case is a law unto itself and must be judged and treated individually; that probably most of the procedures advocated will be of benefit if used in those cases to which they are adapted; that no single procedure will benefit all, and that there will always be a certain percentage which will be unimproved or even made worse by any operation.

Short-circuiting operations and colectomy may have very far-reaching ill effects in some cases and should be done only after careful thought.

Finally, there seems to be no class of surgery in which the surgeon can use well balanced surgical judgment and common sense to greater advantage.

Book Reviews.

Cystoscopy and Urethroscopy for General Practitioners. By BRANSFORD LEWIS, B.S., F.A.C.S., Professor of Genito-Urinary Surgery, Medical Department of St. Louis University, St. Louis, Mo., Genito-Urinary Surgeon to St. John's Hospital, etc.; and ERNEST G. MARK, A.B., M.D., F.A.C.S., Professor of Genito-Urinary and Venereal Diseases in the University Medical College, Kansas City, Missouri, etc.; with a chapter by WILLIAM F. BRAASCH, M.D., Attending Physician to the Mayo Clinic, Rochester, Minnesota. With 113 illustrations, 23 of which are printed in colors. Philadelphia: P. Blakiston's Son and Company, 1012 Walnut Street, 1915.

This book is of real value to those interested in the subject matter it contains. It devotes its first seven chapters to as complete and satisfactory a

summary of the history, development and present-day knowledge of cystoscopy as we have seen. The last five chapters, which are devoted to urethroscopy, are equally well treated, and are most timely at this moment, when for the first time in this country the pathology and treatment of urethral conditions are receiving the attention their importance deserves. Paper, type and illustrations are all most excellent, and the publishers as well as the writers are to be congratulated for the good quality of their work.

Pyelography (Pyelo-Ureterography): A Study of the Normal and Pathologic Anatomy of the Renal Pelvis and Ureter. By WILLIAM F. BRAASCH, M.D., Mayo Clinic, Rochester, Minn. Octavo volume of 323 pages, containing 296 pyelograms. Philadelphia and London: W. B. Saunders Company, 1915.

Dr. Braasch's book is chiefly valuable for the large number and the excellent quality of its illustrations, which show the renal pelvis in its normal state, and in a great variety of abnormal and pathological conditions. The material comes from the Mayo Clinic at Rochester, Minnesota, and the pictures, although they are numerous, are still a careful selection from a great mass of work done during the last five years. The text of the book is written in a simple, pleasant fashion, which makes the reading of it easy and at the same time provides a large amount of information in a small number of words. It contains chapters on the history and technique of this comparatively new field of work, and also chapters devoted to a consideration of the normal and abnormal anatomy of the renal pelvis and its many pathological conditions. There is a very complete bibliography of the subject as well as a good index at the end of the book. The publisher's work is well done.

General Medicine. Edited by FRANK BILLINGS, M.S., M.D., and J. H. SALISBURY, A.M., M.D. Series 1915. Chicago: The Year Book Publishers, 1915.

This is the first volume in the practical medicine series of the current year on the past year's progress in medicine and surgery. It consists of a series of chapters on infectious diseases and diseases of the lungs, heart, arteries, blood and hematopoietic organs, ductless glands and kidneys, and metabolic diseases. Each chapter presents the details of the most important advances made in its domain during the past season. The work is illustrated with twenty-four figures in the text and eight special plates and constitutes an excellent epitome of recent progress in general medicine.

An Introduction to the Study of Color Vision.

By J. HERBERT PARSONS, D.Sc., F.R.C.S., Ophthalmic Surgeon, University College Hospital. New York: G. P. Putnam's Sons. 1915.

This is a book on color vision long needed. Most of the vast literature on the subject has been written to advance some theory; facts have been twisted and objections minimized to favor some authors' views.

This work gives a practical summing up of what we know about color vision and its anomalies without prejudice, and a clear and fair discussion of the leading theories of color blindness. So fairly is this done that one cannot gather what theory Mr. Parsons inclines to. Nor is the book a collection of quotations; it is a lucid and detailed exposition of a complicated subject amply illustrated.

This work is divided into three parts: (1) Chief facts of normal color vision; (2) Chief facts of color blindness; (3) Chief theories of color vision.

A Text-Book of Medical Chemistry and Toxicology.

By JAMES W. HOLLAND, M.D., Emeritus Professor of Medical Chemistry and Toxicology, Jefferson Medical College, Philadelphia. Fourth Edition, Thoroughly Revised. Philadelphia and London: W. B. Saunders Company. 1915.

The new fourth edition of Holland's work maintains the excellence of typography and illustrations to which we have been accustomed in previous editions. An effort has been made to cover the entire subject of chemistry as it applies to medicine and many of the newer tests have been incorporated, thus bringing the work up to date.

It may be seriously questioned, however, whether such a work fulfils the present needs of the medical student when practically all schools are introducing a premedical year where chemistry is taught more as a science than an appendage to medicine. The short introduction to physics which the author's book also contains is rendered useless by the vastly better instruction which the student obtains in that subject in the preliminary training, now demanded by medical schools for entrance. In other words, such medical chemistries, as they are called, are a relic of the past and have outlived their usefulness. At present physiological, organic chemistry and toxicology are independent subjects which can not be well grouped in one work without doing injustice to one or more of them.

Still as long as all medical schools have not adopted the new requirements, such a table d'hôte course as is offered by books of this class

will be needed and one must confess, in all honesty, that this work is one of the best published. The color reactions are portrayed with unusual vividness and accuracy and the description of reactions are lucid and clear cut. There is an excellent index and as a book of reference much as we use an encyclopaedia for a brief and rapid refreshing of our knowledge of a subject within its scope, the work has a merited place in our libraries.

A Manual of Physiology.

By G. N. STEWART. Seventh edition, 1132 pages, 467 figures. New York: William Wood & Co. 1915.

The seventh edition of this excellent manual retains the features which have made earlier editions valuable. Chief among these may be mentioned the exceptionally readable manner in which fundamental experiments are described. The author has been remarkably successful in his discussion of the evidence on which his conclusions are based. The advanced student of physiology, who does not wish to take the time to consult original sources, will find the most significant data in almost any of the important fields of physiology, clearly presented. The new edition differs from previous editions mainly in its chemical aspects. Chemical physiology is advancing very rapidly at the present time and no textbook of physiology can hope to be entirely satisfactory in its chemical material unless subject to frequent revision. The new work along these lines seems to be as fully treated in this manual as in any of its contemporaries. From the standpoint of construction the book is quite satisfactory. Typographical errors and mistakes in indexing, which are often so annoying, are noteworthy by their absence. The figures are excellently selected and well printed.

Evolution and Disease.

By J. T. C. NASH, M.D., (Edin.) New York: William Wood & Co. 1915.

This monograph is based on the author's three Chadwick lectures on "The Evolution of Epidemics," delivered in April, 1913. In the present volume the subject material of these lectures is expanded into a series of sixteen chapters tracing successively the steps in the history of disease and its relation to the evolution of civilization from the times of medieval famine and pestilence through the development of bacteriology and sanitation to the present phenomena of war and military medicine in their bearing on the future welfare of mankind. The book closes with a valuable alphabetic bibliography of references. It is an interesting and useful contribution to the philosophy of evolution in the relation of disease and its control to human progress.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Saturday, from one to two-thirty p.m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

GOLDSMITH AS A PHYSICIAN.

AMONG the famous men of letters whom the medical profession has, with varying degrees of justice, been proud to claim as its members, few, perhaps, have a more charming individual personality, greater genius in writing, and less claim to the distinction of being a physician than Oliver Goldsmith. It has been customary to speak casually of Goldsmith as a doctor, yet the evidence of his medical studies and practice has hitherto hardly seemed to justify his inclusion under that denomination. Indeed, in 1896, Dr. John Morris of Baltimore published in the *Journal of the American Medical Association* (Vol. xxvi, pp. 953-57) a discussion of the question "Was Goldsmith a Physician?" and concludes that "after very faithful research, with an honest hope that I could discover proofs of his having obtained a medical degree, I am constrained to declare that his education did not

fit him for a professional life, or that any university, under the most lax conditions, could have granted him a degree."

Recently, however, at a meeting of the historical section of the Royal Society of Medicine, Sir Ernest Clarke presented in a paper the result of his extensive and painstaking investigations into a multitude of original manuscript sources, as a result of which he seems conclusively to have refuted Dr. Morris's conclusion. It seems definitely disproved that Goldsmith obtained his medical degree at Padua, at Leyden, at Edinburgh or at Louvain. Dr. Clarke has, however, found irrefutable evidence that he did receive such a degree from Trinity College, Dublin, and this evidence he presents in conjunction with a brief sketch of Goldsmith's career.

Oliver Goldsmith was born in Dublin on November 10, 1728, was admitted to Trinity College on June 11, 1745, and received the degree of bachelor of arts on February 27, 1749. Immediately after this he read for orders for a short time and then served for a year as tutor in a gentleman's family of the neighborhood. It then appears that he was desired by his uncle to undertake the study of physic, and to this end he went to Edinburgh, probably in 1752. Several of his letters are preserved from the period of his residence at Edinburgh, and in these he speaks from time to time of his medical studies and teachers, particularly of Mr. Munro, professor of anatomy, "the only great man among them; so that I intend hearing him another winter, and go then to hear Albinus, the great professor at Leyden." The name of Oliver Goldsmith appears twice in the still extant class lists of Professor Alexander Munro, Senior, as having entered the class of anatomy in October, 1752, and again in October, 1753, paying each time a fee of three pounds, three shillings.

As a matter of fact, Goldsmith finally did go to Leyden, and elsewhere on the Continent. In a letter to his uncle, in January, 1754, he says: "After having spent two winters in Edinburgh, I now prepare to go to France the 10th of February: I have seen all that this country can exhibit in the medical way. . . The circle of science, which I have run through before I undertook the study of Physic, is not only useful, but absolutely necessary to the making of a skilful physieian. . . I shall spend this spring and summer in Paris, and at the beginning of next winter go to Leyden. The great Albinus is still alive there, and 'twill be proper to go, though

only to have it said we have studied in so famous an University."

After his visit to Leyden came the fascinating chapter of Goldsmith's wanderings, afoot, through France, Switzerland and Italy, and ultimately his return to England in 1756. He reached London in February of that year, in a state of utter destitution, and succeeded, at first with difficulty, in earning a livelihood as assistant to a chemist on Fish Street Hill, near the London monument. Later, through the patronage and friendship of a Dr. Sleight, he set up in medical practice in Southwark, where he seems to have lived a hand-to-mouth existence under very shabby and precarious circumstances. The *Lancet*, in its issue of March 7, 1914, presents the following sketch of Goldsmith during this period of his career:—

"Reynolds once told an anecdote of the care with which Goldsmith at this time carried his hat so as to hide a patch in his coat. He tried all kinds of other employments, from that of usher to that of printer's reader, but returned as a *pis aller* to the medical profession, for which he had so little gift and for which he was at this time not 'qualified', as the word is now understood. In December, 1757, he writes to his brother-in-law Hodson that he was making shift to live by a 'very little practice as a physician, and a very little reputation as a poet.' In August, 1758, he wrote three letters to friends in Ireland, begging them to get him subscribers for his forthcoming book, 'On the Present State of Taste and Literature in Europe.' The MS. of one of these letters was reproduced in 1858 by the modern representative of Griffin, Goldsmith's original publisher. It probably has often been torn from the collected edition of Goldsmith printed by Griffin in 1858, and has deceived the unwary collector of autographs. In this letter, which is addressed at great length to Mrs. Lawler, *née* Contarine, the cousin with whom poor 'Goldie' had been in love in Ireland, he gives an account of his penury, none the less poignant for its tone of persiflage. He intends, he says, to adorn his room with 'maxims of frugality.' 'These,' he continues, 'will make pretty furniture enough and won't be a bit too expensive, for I shall draw them all out with my own hands, and my landlady's daughter shall frame them with the parings of my black waistcoat. Each maxim is to be inscribed on a sheet of clean paper and wrote with my best pen, of which the following will serve as a specimen: "Look sharp. Mind the mean (*sic*) chance. Money is money now. If you have a thousand pound, you can put your hands by your sides and say you are worth a thousand pounds every day of the year. Take a farthing from an hundred pound, and it will be a hundred pound no longer." Thus which way soever I turn my eyes they are sure

to meet one of those friendly monitors, and as we are told of an actor who hung his room round with looking-glasses to correct the defects of his person, my apartment shall be furnished in a peculiar manner to correct the errors of my mind.' The sale of his book was to pay for his passage to Coromandel, where, through his friend Milner, he had obtained the position of physician and surgeon to a factory. His practice was to bring him in £1000 per annum, but evidently he was expected to qualify first. He must have been familiar with Smollet's description of an examination at Surgeon's Hall in 'Roderick Random,' but undeterred by this he presented himself before the examiners and was disqualified. The examiners were probably Messrs. Mark Hawkins, Fullagar, Nourse, Girle, Singleton and Roul. The entry in the Royal College of Surgeons 'Examination Book,' under date Dec. 21st. 1758, states that before a Court of Examiners, held at the theatre, James Johnson was 'appointed apprentice to Mr. Carson, Thomas Meggs qualified for surgeon to a regiment, James Bernard Mate to an hospital, Oliver Goldsmith, found not qualified for Do.'"

With this failure before the Royal College of Surgeons Goldsmith's medical career in London came to an end and the Coromandel venture failed also to materialize. Goldsmith's movements during the ensuing years are, to a great degree, uncertain, but in the diary of Bishop Percy (editor of the *Reliques*) are memoranda of his meeting Johnson and Goldsmith at Oxford in February, 1769, and under the date, February 18, "On this occasion Dr. Goldsmith was admitted as *cumdem gradum*, which he said was M.B." From this it would appear that Goldsmith actually received a medical degree from Oxford and that he had previously received one from some other medical college. With the assistance of Sir William Osler, Dr. Clarke now proceeded to search the files of the local newspapers and was rewarded by finding at last, in the issue of Jackson's *Oxford Journal* for Saturday, February 18, 1769, the following conclusive item:—

"Yesterday Oliver Goldsmith, Esqr., Bachelor of Physick in the University of Dublin, author of *The Traveller a Poem*, of the *Present State of Polite Learning in Europe*, and of several other learned and ingenious performances, was admitted in Congregation to the same Degree in this University."

It appears certain, therefore, that Goldsmith must have received his medical degree in Dublin at some time between 1756 and 1763, probably in 1761, since shortly after this date appears his first signature in an agreement with

his publisher as Oliver Goldsmith, M.B. The *ad eundem* degree granted him at Oxford was doubtless given rather for his distinction in letters than in medicine.

In the discussion of Sir Ernest Clarke's paper Mr. D'Arcy Power presented the following clinical data with reference to the cause of Dr. Goldsmith's death: "Goldsmith had long been troubled with symptoms of renal disease, and as early as 1770 to 1771 he had spent some time at Bath, probably for the cure of a 'gouty kidney.' In 1773 he was suffering again from dysuria, but he improved under treatment, and in March, 1774, he went to a farmhouse at Hyde, near Handon. Here he was taken ill on March 25, becoming feverish and having a fresh attack of dysuria. He seemed so weak and his pulse was so bad that his apothecary became frightened and sent for further advice. A little improvement took place, but the patient persisted in dosing himself with James's powder—a preparation of antimony which he had himself recommended in 'Little Goody Two Shoes.' At midnight on Sunday, April 3, he was in a sound and calm sleep, but his condition clearly caused anxiety, because 'the gentleman who attended him' was on the alert, and at 4 p.m. he was found to be in strong convulsions, which continued without intermission until his death at 4.45 a.m. on April 4, 1774. The report of the case has been submitted to Dr. Philip Hamill, the medical pathologist at St. Bartholomew's Hospital, who replied that the symptoms strongly suggested a bacillus coli septicæmia from an old pyelitis, complicated by excess of antimony in the James's powder. From our knowledge of Goldsmith's manner of life, however, it would seem more likely that his terminal condition was one of uremia.

Goldsmith is buried near the old round church of the middle temple in London, and it has recently been proposed to set up near by a replica of the statue of him which stands with that of Edmund Burke at the gateway of Trinity College, Dublin. The final discovery, after this admirable piece of research in medical history, that Goldsmith's medical degree was genuinely obtained from his *alma mater*, should stimulate interest in this project among physicians of all English speaking countries, since the renown which he attained in the field of letters may now justly be held to extend some of its distinction to the medical profession, of which Goldsmith was truly a member.

PROPORTION OF MENTAL DEFECTIVES AMONG DELINQUENTS.

WE have been hearing very much in recent years of the relationship of mental defectiveness to delinquency. Some enthusiasts in this work have been making sweeping and positive statements concerning the very great frequency of mental defectiveness among delinquents. In fact, from some quarters the impression has been spread broadcast that most delinquents about the age of puberty and adolescence are feeble-minded more or less. Those who have not directly dealt with these delinquents, however, have suggested that these statements were exaggerated. No reliable studies seemed to be forthcoming concerning the real proportion of mental defectives among delinquents. Recently, however, a careful study of the proportion of mental defectives among delinquents has been made by a careful worker in this field.

Augusta F. Bronner of the Psychopathic Institute of the Juvenile Court of Chicago, presents such a report as a result of special research work with this single object in view (*Journal of American Institute of Criminal Law and Criminology*, November, 1914). Most of the studies that have appeared up to date cannot be accepted as giving accurate or reliable information. The percentage of feeble-minded among offenders has been ranged so high (even as high as 89%) because some of the following factors have been neglected: Only the caught offender has been considered in most cases. The majority of the data have been based upon the study of those institutions (reformatories and state industrial schools). Those who were not caught and those who were paroled were not considered. Thus the figures for such a highly selected group of offenders are no criterion for offenders in general. Furthermore, the fact has been lost sight of that examination of adolescents and adults by the Binet-Simon tests alone is unsatisfactory for several reasons. These tests are unreliable for the ages above ten years; the coöperation of the examiner must be obtained and this is by no means always easy; the attitude of the examiner may not be such as to gain the confidence of the subject, especially if the examiner himself is much hurried; the examinee's reactions may be considerably influenced by his emotional condition, particularly if he knows that he is to appear shortly before the judge. Furthermore, when it comes to court work, such important factors as defective vision,

defective hearing, mental dulness from physical illness and the pernicious effects of bad habits are likely to be overlooked. In addition, the language factor is a very important one, since the individual may be unable to understand the test or to explain himself properly.

Miss Bronner's research was carried on at the Psychopathic Institute of the Juvenile Court of Cook County, where she probably had to deal with a much less selected group of offenders than can be found elsewhere, her group consisting of first offenders as well as recidivists, and those brought to court on complaint of parents in addition to those caught in delinquency. For the purposes of her research she examined 505 cases of delinquent boys and girls in the Detention Home. She made certain that these children were not to appear in court on the day of the examination, and that they did not know that the examination had any reference to their trials. She took the further precaution to see to it that all the tests were made by the same individual, and in every case allowed sufficient time for the establishment of a feeling of friendliness before the tests were started.

In order that a boy or girl should be classed as normal, he or she had to be so regarded by the physician, the probation officer and the teacher, the child must have reached at least the sixth grade, there must have been no retardation, and the individual had to be able to do fairly advanced school work. These requirements were demanded in order that chances of error could be excluded. Furthermore, in doubtful cases, the Binet tests were employed. In cases where language proved to be a great factor, other tests not involving language were supplemented. In this way the investigation was scientific and the child was being given a square deal. As a result of these tests, the percentage of feeble-minded was found to be less than ten, while the group of those normal in ability was found to exceed ninety per cent.

WORK OF THE MASSACHUSETTS ANTI-TUBERCULOSIS LEAGUE.

As the principal publication in this week's issue of the JOURNAL we are pleased to present the proceedings and principal papers of the first annual meeting and conference of the Massachusetts Anti-Tuberculosis League held in this city on Thursday, April 1, 1915. This new organization is intended to coordinate the work of

local anti-tuberculosis societies throughout the state, and by its annual meeting to encourage the report of investigation and progress and the dissemination of knowledge of methods in dealing with tuberculosis in the community.

Among the original papers presented, especial attention should be called to those of Dr. Allan J. McLaughlin, Dr. John B. Hawes, and Dr. Walter G. Phippen on the situation in regard to the new local tuberculosis hospitals and dispensaries. At the time these papers were presented a large number of the communities coming under the provisions of the act of 1911 had failed to take steps to establish such institutions as required by this law. Since that time, however, as has been noted in current issues of the JOURNAL, various of these cities and towns have undertaken compliance with the regulation and it is expected that by September 1, all will have done so.

Mr. Arthur Drinkwater, the treasurer of the Association, reported a balance of \$1,277.56 in its finances, chiefly derived from the sale of Red Cross Christmas seals. Owing to the generosity of the Boston Society for the Relief and Control of Tuberculosis, the expenses of the Massachusetts Anti-Tuberculosis League for this year have been comparatively light. Mr. Drinkwater pointed out that the League, if adequately financed, can be of great service to the state and to local anti-tuberculosis associations; but that individual support will be necessary if the opportunities for service afforded by the League are to be adequately employed. The following officers of the association were elected for the ensuing year:—

President, Vincent Y. Bowditch, M.D., Boston; vice-presidents, Walter P. Bowers, M.D., Clinton; James C. Coffey, Worcester; Rev. William B. Geoghegan, New Bedford; John H. Gifford, M.D., Fall River; Mrs. Joshua Hale, Newburyport; Miss Louise P. Loring, Beverly; Allan J. McLaughlin, M.D., Boston; George L. Schadt, M.D., Springfield; secretary, Seymour H. Stone, 4 Joy Street, Boston; treasurer, Arthur Drinkwater, Cambridge; executive committee, Roger I. Lee, M.D., Boston, chairman.

The secretary of the League, Mr. Seymour H. Stone, reported that the League now represents thirty-four anti-tuberculosis associations throughout the state. The important future possibilities of the work of this organization are hardly to be over-estimated, and it is a pleasure to record in the JOURNAL this first earnest of its purposes and aims of service.

THE CONQUEST OF TYPHUS IN SERBIA.

THE JOURNAL has the unique and valuable privilege of publishing, in another column of this week's issue, a series of extracts from private letters of Dr. Richard P. Strong, written during the period of his service in Serbia in charge of the sanitary commission for the eradication of typhus fever. These extracts are chronologically arranged and present in the form of a diary letter an intimate and first hand personal record of Dr. Strong's work. In a recent issue of one of the Boston daily papers there appeared similar extracts from a diary kept by Dr. Strong, which presented, however, other aspects of the work from those shown in these letters. Referring in this diary to a trip of inspection Dr. Strong writes as follows of his experience in traveling by handcar from Ferrosoviez to Uskub:—

"We started at 4 a.m., but after we had been running an hour one of the iron thwarts in the wooden handlebar of the handcar suddenly broke. Happily we were running down hill and he car kept on going until we reached the next station. Here we found a blacksmith and within an hour he had welded the broken parts together."

After his return to Nish from this tour of inspection he writes also as follows in the diary with reference to his methods of disinfection:—

"I am glad to say that my transportable disinfecting and bathing plants have just been finished and will be sent to Uskub tomorrow for use. Such a plant consists of a car which contains a boiler for generating steam; a second car, formerly a refrigerating car, which is practically a huge autoclave, and into which the steam is turned for the disinfection of clothes, and a third car in which there are 15 shower baths."

"The individuals are to have their hair clipped, be bathed and their clothes disinfected by steam while they are bathing. Their clothes will be ready after the bath. Before they clothe themselves they are sprayed with petroleum. Several thousand persons can be bathed and disinfected in a day by this means and the cars can be moved from city to city. I used to utilize cars with steam disinfection in Manchuria."

The work done by Dr. Strong and his associates, in the prompt control and eradication of typhus fever in Serbia, is thus far the greatest medical service of the present war and is comparable with the work of Reed on yellow fever in Cuba, of Gorgas in Panama, and of Dr. Strong himself on pneumonic plague in Manchuria. By his achievement, not only was relief brought to a nation menaced by a terrible

epidemic scourge, but the extension of that epidemic to other countries and peoples, with its consequent incalculable potentialities of suffering and loss of life, was prevented, a triumph of medical science in time of war.

EYE INJURIES IN WARFARE.

SOME of the most distressing wounds which have been reported from the European arena of war are those of the orbit. Not only are these peculiarly painful when inflicted, but they result usually in a much more serious disability than the average wound. It seems that those received by bullets which are wholly or partly "spent" prove to be more serious than those where the initial velocity of the projectile has not been modified. The most serious ocular injuries of all are those received as a result of enflaming fire, where both orbits are pierced transversely. Eyelid injuries are also common, and in these the lids usually become so edematous that sutures cannot be applied.

Sympathetic ophthalmitis has practically been abolished as a result probably of the early diagnosis and treatment of injured eyes, the application of the principles of asepsis and the prompt enucleation of ruptured globes. Students of medical history will recall that this affection was extremely prevalent during our Civil War, occurring in about 16% of all eye injuries.

The penetration of the eyeball by small foreign bodies is a very common occurrence and often gives more trouble in treatment than what are apparently more serious injuries. The body is usually a fragment of the steel or cupronickel coat of a bullet, although it often happens that dirt and gravel are driven through the choroid by the explosion of a shell. There are two main difficulties in the treatment of such cases. First the intruder must be located, and this is sometimes almost impossible to do definitely, even though two or three skiagraphs are taken, the foreign body being too small to cast an appreciable x-ray shadow. Even after the particle is located it may not be feasible to remove it intact, owing to its friability, and sometimes when it is removed there is found to remain another foreign body whose existence had not been suspected. Many such fragments, too, are non-magnetic and hence cannot be removed by the electromagnet.

MEDICAL NOTES.

AMENDMENT OF THE HARRISON LAW.—Report from Washington, D. C., states that on July 30 the federal regulations under the Harrison narcotic law were so changed as to permit the registration of osteopathic practitioners to administer narcotic drugs in those states in which they are admitted to register as physicians.

DECLINE IN PRICE OF RADIUM.—In another column of this issue of the JOURNAL we note a further recent advance in the cost of various drugs and their preparations. Strangely enough, advice from London on July 20 states that the price of radium has declined during the past year about \$1000 a gram, apparently, because the war has forced some holders of limited quantities to sell at a loss. Meantime in America the experimental station of the United States Bureau of Mines in California has succeeded in producing radium from carnotite ores at a cost of only \$36,000 a gram, a rate greatly lower than that of the European products which have ranged in price from \$120,000 to \$160,000 a gram.

FEEBLE-MINDEDNESS IN OHIO AND INDIANA.—The recently published eleventh bulletin of the Massachusetts State Board of Insanity for July, 1915, calls attention as follows to the status of feeble-mindedness in Ohio and Indiana: "In a publication of the Ohio Board of Administration, under date of March, 1915, the feeble-minded problem in Ohio is discussed. Ohio estimates 10,000 to 15,000 feeble-minded in that state, with the state taking care of only 2000 in institutions, or less than 20%, although some of the others are in reformatories and other institutions. The mental examination of delinquents in the Girls' and Boys' Industrial School and Home reveals startling results. Of 100 girls examined, 59 were feeble-minded, 14 borderline cases, 13 mentally retarded, and only 14 of normal mentality. Investigations among adults have shown that over 50% of prostitutes, 25% of reformatory and penitentiary inmates, and probably 75% of infirmary inmates are feeble-minded."

"The Indiana State School for feeble-minded Fort Wayne, is filled to its capacity and has on the waiting list more than 50 who cannot be accommodated. Dr. George S. Bliss, Fort Wayne, the superintendent, recommends that the state purchase a new farm of one or two thousand acres, to be used in conjunction with the one at present in use. The new farm is needed especially for adult females."

PREVALENCE OF MENINGITIS, POLIOMYELITIS, SMALLPOX AND TYPHOID FEVER.—The weekly report of the United States Public Health Service for July 23, 1915, notes that during the month of June in that year eight cases of cerebrospinal meningitis were reported in Wisconsin

and five in Maryland. During the same month there were three cases of poliomyelitis in Maryland and fifty-six of smallpox in Wisconsin. There were ninety-four cases of typhoid fever in Maryland, sixty-two in New Jersey and forty-three in Wisconsin.

SMALLPOX VACCINE AND TETANUS.—Dr. John F. Anderson, in a recent issue of the *Bulletin of the United States Public Health Service* records his experiments to disprove the validity of the often quoted statement that inoculation for smallpox may ultimately result in tetanus. An experiment of charging smallpox vaccine with tetanus spores and inoculation with it of monkey and guinea-pigs failed to elicit any case of tetanus. In turning to statistics Dr. Anderson found that during the given period the manufacturers had sold for use about 40,000,000 individual doses, of which 32,000,000 were not returned, presumably having been used. Inasmuch as the number of authentic cases of tetanus following inoculation for smallpox was 41, it would show that about one in a million of the persons vaccinated developed tetanus. In the army and navy, during the nine years ending with 1913 there were vaccinated 360,000 soldiers and 225,000 sailors, with corresponding figures of tetanus infection of six and two. The two cases occurring in the navy were found to follow, one a railroad injury and the other a wound. Dr. Anderson's conclusion, therefore, is that tetanus occurring fifteen to twenty days after vaccination does not take its infection from the virus, and there can be no demonstrable connection between smallpox vaccine and tetanus. That the vaccination wound may be the point of entry of the tetanus germ is not disputed, but the possibility of keeping the wound clean is obvious.

EYE, EAR, NOSE AND THROAT HOSPITAL, NEW ORLEANS, LA.—The Eye, Ear, Nose and Throat Hospital of New Orleans, La., which treats only those too poor to pay for medical advice, states in a recently issued report, that during the year 1914 it received 8136 patients, 3333 in the eye department, 4750 in the ear, nose and throat department and 53 dermatological cases; 188 operations were performed. A total of 4,796,000 units of diphtheria antitoxin were dispensed to 638 patients, which was an increase of more than 1,000,000 units over the year 1913.

EUROPEAN WAR NOTES.

SERBIAN SANITARY COMMISSION.—It is announced that Dr. Harry Plotz and Dr. George G. Bohrer, of the Mt. Sinai Hospital, New York recently sailed from that city aboard the Greco steamer *Themistocles* to join Dr. Richard L. Strong at Nish, taking with them a complete bacteriologic outfit for use of the Serbian sanitary commission.

WITHDRAWAL OF AMERICAN RED CROSS UNITS.
—In last week's issue of the JOURNAL we published a statement announcing the intended withdrawal of American Red Cross units from Europe on Oct. 1. The following further statement recently issued by Miss Louisa P. Loring, Red Cross emergency secretary for Massachusetts, indicates, however, that Red Cross relief work in Europe will not be wholly suspended:—
"Since the report was printed that the Red Cross was to withdraw its personnel from Europe by Oct. 1, there apparently has been a misunderstanding on the part of some persons who take it for granted that the Red Cross work for Europe would then be finished. On the contrary, the Red Cross will continue to send supplies, but the units of surgeons and nurses are to be withdrawn, as the following letter received from Miss Boardman clearly explains:—

"Dear Miss Loring—After a year's service in Europe the American Red Cross has considered it advisable to withdraw our personnel with the exception of those in Belgium, who have been here only about six months. On Oct. 1 we would have to change many of our surgeons and nurses, if not all of them, as their tours of duty would be up. To bring those we have in Europe home and to send out substitutes would cost a total of perhaps \$70,000, and then we should not be able, with our present funds, to maintain these units in Europe but two or three months longer than Oct. 1. For this reason it has seemed advisable to utilize what money we have left in sending the necessary supplies to Europe and aiding the Red Cross societies there by contributions of funds. We have notified the governments long in advance, to give them ample time to take over the hospitals which our personnel have occupied. Yours, etc.,

"Mabel T. Boardman, Acting Chairman."

"Much as it regrets this necessity, the society realizes that no Red Cross of a neutral country ever before rendered so long and extensive service in the way of personnel to nations engaged in war.

"The sanitary work in Serbia will continue."

ANNUAL REPORT OF AMERICAN RED CROSS.—On July 29 the American Red Cross published in New York an annual report dealing with the last year of its war activities in Europe:—

"Since hostilities began, the American Red Cross has spent \$1,460,306 for relief of suffering people to the war, leaving on hand a balance of \$74,818. Never in history has a Red Cross organization rendered so great a service to the peoples of other countries. Every country engaged in the war is represented in the expenditure of the great fund.

The personnel now in Europe totals 71 surgeons and 253 nurses, and of these all but about 100 surgeons and twenty-four nurses will be recalled not later than Oct. 1 next.

The financial statement covering the year's work is as follows:—

RECEIPTS.	
Contributions	\$1,560,124
Special for Serbian Agricultural Relief Committee	10,000
Special for the Rockefeller Foundation for the Sanitary Commission	65,000
Total	\$1,635,124
(The Rockefeller Foundation also contributed \$20,000 additional directly to the Commission in Serbia.)	
EXPENDITURES.	
Cash remitted	\$423,882
Designated contributions	\$217,182
Undesignated contributions	206,700
Salaries of surgeons and nurses	216,018
Travel and maintenance of personnel; transportation of supplies on land and sea, including freight, drayage, expressage, lightering, pilotage, etc.	148,472
War insurance	10,128
Equipments and outfits	36,298
Supplies purchased	354,630
Appropriated for pensions for the widows of two American Red Cross doctors who died of typhus while on duty in Serbia	15,000
Miscellaneous	2,375
Sanitary Commission—Appropriated for transportation, equipment, supplies, salaries and maintenance	105,000
Designated contributions to be remitted	8,493
Salaries and maintenance for three months additional and return of personnel (estimated)	140,000
	<hr/> 1,460,306
Balance	\$ 74,818

The report also includes an itemized list of all the articles shipped to Europe by the American Red Cross, a list in which are hundreds of articles having to do with medicine, surgery, sanitation, and other phases of Red Cross work.

Bandages	1,966,000
Antiseptic tablets	1,150,000
Cotton, pounds	892,670
Hospital garments	211,688
Surgical dressings and pads	1,106,516
Sulphur, pounds	358,982
Clothing for refugees (garments)	269,963
Gauze, yards	1,062,281
Anesthetics, pounds	31,191
Adhesive plaster, rolls	11,345
Handkerchiefs	22,412
Pillows	22,400
Blankets	13,876
Antitoxin, cases	71
Alcohol, gallons	1,034
Cholera vaccine, doses	12,200
Hospital linen, articles	49,548
Mufflers	29,341
Smallpox vaccines, tubes	10,000
Soda, pounds	20,000
Slings	19,810
Crimoline, yards	67,415

The list includes, it is stated, supplies purchased and donated, designated as well as undesignated, but does not include supplies still waiting shipment to the warehouses of the Red Cross."

CONDUCT OF BRITISH ARMY MEDICAL SERVICE.
—In a dispatch dated June 15, and published in the *London Gazette* on July 10, Sir John French commented in the following terms of commendation on the conduct of the British Army Medical Service at the front:—

"I have much pleasure in again expressing my warm appreciation of the admirable manner in which all branches of the Medical Services now in the field, under the direction of Surgeon-General Sir Arthur Sloggett, have met and dealt with the many difficult situations resulting from the operations during the last two months.

"The medical units at the front were frequently exposed to the enemy's fire, and many casualties occurred amongst the officers of the regimental medical service. At all times the officers, non-commissioned officers and men, and nurses carried out their duties with fearless bravery and great devotion to the welfare of the sick and wounded.

"The evacuation of casualties from the front to the base and to England was expeditiously accomplished by the administrative medical staffs at the front and on the lines of communication. All ranks employed in units of evacuation and in base hospitals have shown the highest skill and untiring zeal and energy in alleviating the condition of those who passed through their hands.

"The whole organization of the Medical Services reflects the highest credit on all concerned."

HIGH DEATH RATE AMONG BRITISH WOUNDED.

—In the issue of the *Lancet* for July 17 the following comment is made on the relatively high death rate prevailing among British wounded in the war:—

"The fact, related in Parliament by Mr. Asquith, that the proportion of deaths among our wounded amounts to nearly 24% has naturally caused a painful impression. We have already pointed out that the percentage of deaths during the Crimean War was only 22, and this in spite of the appalling insanitary conditions which then prevailed. This proportion was reduced to 20% during the Boer War, but 44 years ago, during the Franco-Prussian War, the Germans lost only 17.53% of their wounded. The introduction of aseptic and antiseptic surgery and the great progress generally accomplished since then, made it only reasonable to expect an even greater saving of human life.

"But in spite of the figures quoted by Mr. Asquith in the House, the anticipated improvement has taken place; given conditions similar to those that prevailed in 1870-71, we may confidently say that the percentage of deaths is less now than then. But conditions generally are utterly different today. The trench fighting results in a much larger number of injuries due to shells and shrapnel. Wounds from rifle bul-

lets are comparatively rare, and when they do occur the body is so sheltered by the trenches that it is generally the head which is hit, and the probability of fatal results is consequently much greater. But by far the most terrible feature of the present war is the fact that in so many cases it is absolutely impossible to bring timely help to the wounded. The trenches face each other at very short distances. An attack is delivered and the mass of the wounded fall on the unsheltered space between the trenches. When the struggle is over this space is carefully watched, and the slightest movement brings a volley from rifles or machine-guns. At night only, when favored by darkness, some of the wounded may be able to crawl back to their trenches. It is the cruel fact that aid reaches the wounded very late, if at all, that accounts chiefly for the high death-rate. It has been suggested that women dressed in some very conspicuous manner might be employed for this purpose, for there would be no possibility of mistaking their pacific purpose. If we could once more fight in the open, where the entire body, instead of merely the head, would be exposed; if the rifle bullet resumed its ascendancy; and if, further, it was possible to relieve all the wounded as soon as the battle was over, we should then doubtless find that the percentage of recoveries among the wounded was in keeping with what we are entitled to expect from the advance in surgical science.

"Especially will this be the case if operations can be performed and absolute rest and full treatment be given for a sufficient length of time close to the battlefield in cases of abdominal and other wounds that are dangerously aggravated by traveling. This, we understand, is now actually done, though perhaps, there is room for some improvement in the shape of more extensive accommodation near the front.

"A greater number of portable tent hospitals will be required, particularly when the armies begin to move. Railway head lines for ambulance trains may not be so conveniently near as at present. Certainly there is an extensive network of railways in the countries over which the armies now in Flanders are likely to move. But the army that retreats will naturally destroy the rails and blow up the bridges when ever possible, and there may even be a scarcity of houses remaining that might serve as temporary hospitals. Battles will probably be fought long before the lines of communication can be repaired. The present facilities for promptly disposing of the wounded by sending them to the base hospitals cannot always be maintained.

"It will not go on forever, and now is the time to prepare for the very different condition that will prevail when we are once again able to carry out rapid movements. Tent hospitals that can be dismantled, packed in carts or railway trucks, conveyed in any direction and put up again in a few hours are likely to be especially useful."

BOSTON AND NEW ENGLAND.

NEW ENGLAND ALUMNI ASSOCIATION OF THE GRADUATES OF JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.—The tenth annual meeting of the New England Association of the Alumni of the Jefferson Medical College of Philadelphia was held at Rocky Point, Rhode Island, July 28. Nearly 100 members were present. An elaborate banquet, arranged by the Rhode Island delegation, was served. Addresses were made by the following: John T. Farrell, Providence, R. I., subject, "Roentgenology"; Wm. H. Green, Class 1864, "Advance in Surgery in the U. S. Navy in the Last 50 Years"; T. F. Fitzmaurice, Lewiston, Me., subject, "Status of the Present Day Surgery of the Eye, Ear, Nose and Throat"; Charles A. Riley, Boston (Tufts College Instructor), subject, "Pulmonary Tuberculosis and Its Proper Treatment: Dietetic, Sanatorial, etc."

Short addresses were made by Drs. P. F. Gahm, Medford, Mass.; E. R. Storrs of Hartford, Conn.; Wallace P. MacCallum of Boston, and Gustave Hartman of Lynn, Mass.

The retiring president, Dr. P. F. Gahm of Medford, Mass., moved for the election of officers. The following were chosen:

President for 1916, Dr. Thos. F. Fitzmaurice of Lewiston, Me.; vice-president for 1916, Dr. E. R. Storrs, Hartford, Conn.; treasurer for 1916, Dr. Frank I. Payne, Westerly, R. I.; secretary for 1916, Dr. Wallace P. MacCallum, 214 Huntington Avenue, Boston, Mass.

The next meeting will probably be held at Hartford, Conn.

WORK OF BOSTON MILK AND BABY HYGIENE ASSOCIATION.—A recently published report by Dr. J. Herbert Young, medical director of the Boston Milk and Baby Hygiene Association, states that of 372 babies under the care of that organization during the fortnight ended July 7, only 28, or 7 per cent., failed to show a gain in weight. "During the past thirteen weeks there have been only two deaths of babies registered with the twelve milk stations of the Milk and Baby Hygiene Association, against nine deaths for the corresponding weeks last year, although the number of babies under supervision twenty per cent. more than the number under care last year. This month 342 new babies came under the care of our doctors and nurses. The number cared for during 1915 to date is 3438."

RECENT CONNECTICUT LEGISLATION.—The recently published seventh bulletin of the Massachusetts State Board of Insanity for July, 1915, calls attention to recent legislation in Connecticut relative to the local care of the feeble-minded. The Legislature of Connecticut has recently passed a law changing the name of the Connecticut School for Imbeciles to the Connecticut Training School for the Feeble-minded, and has

authorized the construction of buildings for said school on the property of the state in the town of Mansfield.

The act states that the Board of Trustees of the Connecticut Colony for Epileptics shall appoint three of their number and the Connecticut Training School for the Feeble-minded shall appoint three of their number, to constitute a commission to locate a site for the erection of buildings suitable for the conduct of said training school, to be near the Colony for Epileptics at Mansfield.

THE APPOINTMENT OF A BOSTON HEALTH COMMISSIONER.—In the issues of the JOURNAL for May 13, June 10, July 1 and July 29 we have published statements alternately confirming and denying the acceptance by Dr. Richard H. Creel, of the United States Public Health Service, of the appointment as health commissioner of the City of Boston. On July 28 it was finally and definitely announced that Dr. Creel has declined this appointment on account of his health. On July 30 it was announced that the position of Boston Health Commissioner has been offered to Dr. Francis X. Mahoney, the present chairman of the health board, and that he has accepted it.

In the original plan for the reorganization of the board of health there was provision for seven departments. This number has now been reduced to five by the transfer of the local quarantine station to the national government, and of the division of child hygiene to the school department. Dr. William J. Gallivan, chief of this division, has resigned and the determination of his successor has not been made. The appointment of the five new department heads, to be known as deputy commissioners, rests with Dr. Mahoney under the approval of the mayor.

Obituary

CHARLES PARKER HOOKER, M.D.

DR. CHARLES PARKER HOOKER, who died of acute myocardial insufficiency with angina, on July 21, at Fortune Rock, near Biddeford, Me., had been for many years a leading medical practitioner in Springfield, Mass., an intensely active man who shortened his life by unflinching devotion to duty. He was a native of Springfield, born there on September 18, 1855, the son of a physician, Dr. John Hooker, one of the well-known local practitioners of his day.

After obtaining his early education in the public schools of Springfield, Dr. Hooker entered the Harvard Medical School, from which he received the degree of M.D. in 1879. He immediately settled in practice at Springfield, where his success was early and permanent. In 1855 he was appointed county physician and held this

position until March, 1915. An obituary notice of Dr. Hooker, which appeared in a recent issue of the *Springfield Republican*, speaks as follows of his hospital service and associations in that city and of his personal characteristics:

"Dr. Hooker served as a visiting physician of the Springfield Hospital during his practice here and was associated with that institution before it was established in its present location. At the recent dedication of the Dr. Frederick Wilcox Chapin memorial building at the Springfield Hospital he paid appreciative and understanding tribute to Dr. Chapin. He was also a visiting physician on the Mercy Hospital staff for two years after the opening of that institution, but retired to give more time to the Springfield Hospital.

"Dr. Hooker was so vital a personality that his departure will be a shock. He was greatly interested in all that concerned the city of which he was a native, and whose life he entered into with the enthusiasm that was characteristic of all he did. While not conspicuously robust, he was what men call 'wiry'. His interest in his profession led him to overwork, and recognition of the need for rest now and then showed that he was overdoing his strength, but it was not known how near the danger line he had come. His going is a loss to Springfield."

Miscellany.

ADVANCE IN COST OF DRUGS.

IN the issue of the JOURNAL for July 29 (Vol. cxxiii, p. 183) we published an extended statement detailing the rise in the price of various drugs which has occurred as a result, directly or indirectly, of the European War. Recent report from New York again announces further advance in the cost of several groups of pharmaceutical preparations notably the coal tar products:

"Perhaps the most extraordinary development in the drug and chemical markets today has been the advantage taken of the pressing needs of domestic and foreign consumers of such coal tar products as carbolic acid, cresylic acid, picric acid, benzoate of soda, benzoic acid, salicylic acid and salicylate of soda, antipyrine, acetanilid, acetphenetidin, cresol, hydroquinone, naphthalene, myrbane oil, artificial musk, synthetic wintergreen (or methyl salicylate), artificial almond and mustard oils, coumarin, thymol, vanillin and phenolphthalein. All local handlers of the above goods are asking substantial premiums over the prices in effect here a week or ten days ago and are asking much higher prices for the goods when it is known they are intended for export than when known to be for home consumption. Sellers insist that purchasers sign contracts guaranteeing that the goods are being taken

solely for home consumption and are not to leave the country.

Manufacturers of caffeine now find themselves practically unable to supply demand owing to the continued call from export sources which has absorbed the bulk of their offerings. Cost of production is also on the increase, owing to the sharp advance in price of tea and coffee from which caffeine is extracted. Prices in this market have consequently risen to a basis of \$7.25 @ \$8 per pound for the alkaloid and \$1.25 @ \$4.50 per pound for the citrated. A few manufacturers are attempting to keep their prices down to \$6.50 for the alkaloid and \$3.35 @ \$3.40 per pound for the citrated.

"Quinine salts rule comparatively strong in the local market on the basis of 30 cents per ounce, although outside lots of German and Java salts can be picked up here as low as 29 1/2 cents per ounce. The imports of cinchona bark from Java and Europe were comparatively small in the first eleven months of the current fiscal year, having totalled 3,436,381 pounds, against 3,250,881 pounds in 1914, while the imports of quinine sulphate and all alkaloids or salts for which quinine can be compounded during the eleven months under review totalled 1,826,533 ounces, against 2,578,185 ounces in the corresponding period a year ago and 3,069,206 ounces in 1913. The demand from domestic and foreign consumers is particularly active and bids fair to continue so for some months to come.

The demand for opium from domestic consumers has fallen to negligible proportions, and a further accumulation of spot stock has resulted. Sellers now quote on the basis of \$7 @ \$7.25 for the gum in cases, while holding the powdered and granular grades for \$8.05 @ \$8.15 and \$8.15 @ \$8.20 per pound, respectively. Rumors that the Turkish government has imposed an embargo on the narcotic persist, but still lack confirmation. A feature in connection with the opium situation was the publication of statistics this week showing that the stock of opium in United States bonded warehouses at the end of May this year stood at 104,668 pounds of the value of \$483,320, comparing with only 20,013 pounds of the value of \$73,434 on the corresponding date a year ago. Opium in bond at the port of Boston on June 30 is reported to have amounted to 217 pounds, valued at \$1137, compared with the same quantity having the same value on the corresponding date a year ago."

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending Aug. 3 1915, are as follows: Diphtheria, 37, of which 9 were non-residents; scarlatina, 21, of which 3 were non-residents; typhoid fever, 8, of which 1 was non-resident; measles, 43, of which 3 were non-residents; tuberculosis, 42, of which 2 were non-residents. The death-rate of the reported deaths for the week was 14.76.

LARREY AT THE BATTLE OF WATERLOO.

IN the issue of the *British Medical Journal* for June 19 appears the following item about the relations of Larrey and Napoleon after the latter's return from Elba, and of Larrey's experience at the battle of Waterloo.

"When Napoleon returned from Elba in 1815 he almost at once sent for Larrey and discussed with him the organization of the ambulances for the forthcoming campaign. But Larrey was made aware that he was to be replaced by Percy as Surgeon-in-Chief of the Grande Armée, and determined to leave the service. Napoleon, however, coaxed him into giving up this intention, and on June 10 he accompanied the Emperor to Belgium. At Ligny it became evident that a mistake had been made in putting Percy in the place of Larrey. Usually before a battle Larrey visited all the places near likely to be suitable for the reception of the wounded, and made all necessary preparations. His experience enabled him to estimate with approximate accuracy the probable number of men who would need attention. Percy, who was exhausted by the fatigues of much campaigning, and who suffered from heart disease besides, was unable to do this. But Larrey himself admits that the best organized ambulance service would have broken down after Waterloo. The surgeons did their best, often under fire and exposed to charges of cavalry. Larrey's chief ambulance was close to the farm of the Belle Alliance, but, as usual, he went about the whole field. While trying to bring off his wounded he received two sabre cuts, one on the head, the other on the shoulder, from a Prussian lancer. He was left for dead on the field, but recovering consciousness tried to make his way to the frontier. When he had reached the banks of the Sambre, and thought himself in safety he was again surrounded by a corps of Prussian cavalry and taken prisoner. They burned the headquarters ambulance at Caillou, where the French wounded had been left. Larrey, who was held in high esteem by the King of Prussia, and who was well known to many German officers, was stripped of his clothes, robbed of his money, his watch, a ring given to him as a talisman by a dying Mameluke after the battle of the Pyramids, a sabre presented to him at Boukir by Napoleon, and even his boots. His hands were tied, and thus, half-naked, bleeding from wounds torn open by the rough treatment to which he had been subjected, he was taken to the general commanding the advance guard. In stature he was almost the same as the Emperor, and he wore a grey overcoat over his uniform; these things, together with the sabre on which the name of Buonaparte was engraved, made the Russians believe that Napoleon had fallen into their hands. To the commandant, Larrey, who spoke a little German, explained who he was

and how the name of Buonaparte came to be on the sabre. Hesitating, but not convinced, that officer sent him on to the general commanding the division. That officer knew the Emperor, but, irritated by the mistake, would listen to no explanations, and ordered Larrey to be shot. Fortunately, a military surgeon, who went to blindfold him as he was standing before the firing squad, recognized Larrey and insisted that the execution should be put off. After some difficulty Larrey was brought before Blücher, whose son he had saved when wounded and a prisoner in 1813. The old soldier apologized, ordered that Larrey's clothes and money should be restored to him, invited him to dinner, and promised to let Madame Larrey know that her husband was safe. He was allowed to go to Louvain, where the municipality and the inhabitants gave him a most flattering welcome. The population of Belgium showed the most practical sympathy with the French wounded. They picked up those who were on the field and conveyed them to the hospitals of Brussels and Louvain. Larrey, as soon as his wounds had healed, asked to have charge of the French wounded in the hospitals of Louvain, and went to Brussels to acquaint himself with the situation of those collected in that town. He found that in many of the hospitals the French wounded were mingled with those of other nations, and that the sight of Prussians lying beside them put them into a state of fury. Every day there were violent scenes in the wards and murderous quarrels took place, a state of things not favorable to cure. Larrey got his fellow countrymen separated from the Prussians and placed together in the military hospital at Brussels. Having operated in a number of difficult cases he went back to Louvain and thence to France, where he arrived on Aug. 15. He found that Blücher had kept his promise and informed his wife that he was safe."

This chapter of adventures sounds almost too romantic to be true, yet it may probably be paralleled by the experiences of individuals in the present war, when these come to be narrated. Doubtless many Napoleonic tales have been considerably heightened by the imagination, a custom common among good story-tellers.

Correspondence.

WORK OF THE SERBIAN SANITARY COMMISSION.

We are enabled to give the following extracts from diary letters of Dr. R. P. Strong to his sister. They were written with no idea of publication, recounting simply the progress and details of his work day by day. These extracts are made as of special medical interest. Much of the deepest interest must be left out for reasons not hard to guess.

He arrived in Nish April 22nd, and found the first work to be done was the organization of a general health board which could supervise and unify work throughout the country.

"April 25th. . . . The present board as it stands consists of Prince Alexander, President; Sir Ralph Paget, Vice President, the chiefs of the French, British, Russian and American commissions, the chiefs of the Serbian Military and Civil Medical Department and a representative from the parliament, with Dr. R. P. Strong, Medical Director.

The rest of the session was occupied in outlining a sanitary campaign.

The first meeting of a group of men which includes a number of different nationalities is always a difficult one, but the results have been as satisfactory as I could hope for. Of course, it is not ideal to have such a large board, but when there are so many different commissions you can see it is absolutely necessary for them to have some representation.

In the late afternoon we moved into our house and are really comparatively comfortable. I do not think there is such a thing as a bath tub in any of the houses in Nish. You can imagine what a relief it is to get into a room that you can feel is not infested with insects.

April 26th. . . . This morning began with another session of the Board of Health at 8.30. We concluded the organization of the Board and divided Serbia into fourteen sanitary districts: The English, French and Russian commissions are to have seven of these and America is to have the other seven, the southern half, or new Serbia. The British have been assigned the military districts with the army, and the French the northern ones. The Board of Health will, of course, control the situation in all the districts; but it is obvious to all that it would not be advisable to have English, French and American doctors working in the same Serbian town; that there would be obvious differences of opinion among the subordinates in regard to the work. I expect to travel all through Serbia and make inspections, and if the work is not going on correctly, then it can be corrected through the Central Board of Health.

I received a telegram from Dr. Jackson that he and Dr. Zinsner had arrived at Salonika, and that the remainder of the party was expected tomorrow. I have instructed him to wire me as soon as all the supplies are landed and the rest of the party arrive, and then to proceed to Skopje. At that vicinity there has, according to reports, been an increase recently in the amount of typhus and I shall therefore employ the work of the commission there first. We have no very accurate knowledge of the amount of typhus in Serbia at the present time. There is a record of the number of cases in the hospitals, but none of the amount of the disease among the civil population and this amount must be very large. By the institution of house to house inspection we shall soon be able to find out something in regard to this in the towns. The Russians have charge of Nish but they have only four doctors for house to house inspection.

April 27th. . . . My third important visit today was to His Royal Highness Crown Prince Alexander.

As the Prince is leaving tonight he remained in his train, which was standing on the side track near the station. . . . After the usual greetings we talked of the sanitary conditions in Serbia. He asked me what I thought of the cholera serum and I gave him my views on the subject, saying I did not think the cholera serum for the treatment of cholera was of very great benefit, but that cholera vaccine had shown itself to be of sufficiently great value to warrant its general employment in a country like Serbia. He asked if I had had any experience in its use, and I gave him results of the work which I carried out in the Philippines with cholera vaccine. He wanted to know something regarding the statistics, and I told him that in towns where we vaccinated one half the population in order to see the effect of the vaccine, the number of cases in the unvaccinated was six times as great as in the vaccinated sections. This method of vaccination was one I devised in Germany in 1903, you may remember, and it is the method

we shall use here in Serbia; that is, we shall use as much of it as I can obtain. It requires only a single inoculation and there is very little local reaction. These are its chief advantages. Its disadvantage is that it is much more difficult to prepare than the old cholera vaccine; but when it is made in a well equipped commercial laboratory this is not the most important factor.

He asked me if I thought that typhus was more dangerous and more difficult to control than cholera, and I told him I thought it was; but that I believed the typhus epidemic could be controlled with proper sanitary measures.

April 28th, Nish. . . . My entire day was spent in an inspection trip. We left here in a motor at 7.40 a. m. I was agreeably surprised at the roads. We were able to run about thirty miles an hour most of the time. In some places the roads were quite bad and we had to go slowly for a few yards. The ride gave me an opportunity to see the country, which is really beautiful and very fertile. There were a great many fruit trees in bloom. Nearly all the land is cultivated; for, as you know, every peasant owns his own land and there are here plenty of sheep and pigs to be seen. Only the women were working in the fields, practically all of the men being in the army.

One sees Austrian prisoners in all these towns. They seem to be allowed to wander about a good deal at will, and generally they appear contented and do not wish to return to fight.

April 29th. . . . Skopje. . . . According to the statistics in the military hospitals here there were 749 cases of typhus yesterday but here also we do not know the condition of the civil population. . . . Immediately after lunch I started out to find buildings I could use for disinfecting plants. I visited everything I could see with a smoke stack in the hope I could find some place where steam could be generated for disinfection, but was unsuccessful. . . . In the evening I dined with the Pagets and some of the members of their hospital staff. Lady Paget came in just as we were sitting down, propped up in her chair with pillows, accompanied by her nurse. She looks worn, and as you know, is convalescing from typhus. She has certainly set as heroic an example as a woman could well do in an epidemic of this kind. She was here when conditions were at their worst and went among the dead and picked out cases of typhus still living and had them carried to her hospital. It was in this way she contracted typhus. . . . She has certainly done magnificent work here. There are 450 cases in her hospital now.

May 1st. . . . I went through the entire Paget Hospital and spent some time examining the typhus cases. A feature, of which almost no mention is made in our text books of medicine regarding typhus, is the occurrence of gangrene of the toes and sometimes about the nose and mouth. Another striking feature is the condition of the pharynx, a swollen appearance of the mucous membrane being observed in many instances in the early stages of the disease. In fact, the mouth requires frequent cleansing with disinfectants. This is another fact which seems to suggest that the virus may sometimes be thrown out into the air into the immediate vicinity of the patient. The nurses working in the hospital are carefully protected by their uniforms and they all wear rubber gloves. I understand they have one piece garments made together with the stockings and over these they wear high boots. It is difficult to see how some of them could become infected with these uniforms. Lady Paget wore such a uniform whenever she went near cases yet she became infected, as did others of the staff of the hospital. . . . There are many Austrian prisoners working about the premises and they have been, I am informed, of the greatest help and assistance. Many of them have had typhus in the hospital itself. I have had the problem staring me in the face since I came here of bathing, disinfecting and sterilizing

ing the clothes of at least three or four thousand people daily, and having their clothes dried for them so they could put them on after their bath. In some of the other towns there have been facilities which could be employed for such a purpose. Thus, in Nish, a brick factory has been employed, the steam being turned into two large iron cylinders in which the clothes were placed. These cylinders were formerly employed for drying the bricks. Here I can find nothing to aid me of this nature. I think I can bring refrigerating cars here and run steam into them as I did at Manchuria. Also, there are no bathing facilities here. . . . Of course, it would be much simpler if we had clean clothing to give the natives after their bath, but we have none and there is no use in disinfecting the individuals unless we disinfect their clothes at the same time. . . .

May 2nd. . . . I understand the motor will arrive tomorrow and I shall certainly need it to visit the surrounding villages. I have had reports today that the epidemic is raging, particularly at Stip and at Pristina just now; that the patients are lying on the floors of various buildings, there being no beds for them and no doctors there. Tonight I must leave for Nish to be at the Board of Health meeting tomorrow. The following day I shall return here and then try to visit Stip immediately. I still have the Montenegro situation staring me in the face. . . .

(The diary May 2nd to May 12th has never been received.)

May 12th. En route to Belgrade. . . . At the beginning of the war Serbia had 400,000 men in the army. She now has 200,000, over 100,000 having died from typhus. At the beginning of the war there were 300 doctors in all Serbia and 121 of these have died. This leaves 239 Serbian doctors for the entire population, which amounts, as you know, to about 5,000,000. So you can see that, with much disease in the land and such unsanitary conditions, we need every doctor we can get. . . . Eventually, when the new American contingent arrives, I think we shall have in the neighborhood of 250 foreign doctors. . . . Am dictating on the train. . . . The country we are passing through looks something like that in France. In the southern part of Serbia one sees now whole fields of wild red poppies and other fields of cultivated poppies. These grow taller than the uncultivated and the flowers are either purple or white. The fruit trees are also in bloom in the southern part of Serbia. In the country we are passing through now there are no poppies. One sees just green hillsides.

May 12th continued. Belgrade. . . . Dr. Ryan met me at the station and came on to the hotel with me. One sees in all the principal streets evidences of the destruction caused by the bombardment; huge holes torn in the sides of many of the public buildings and residences. The Austrians fire a few shells over each day and the Serbians reply with a few. We heard a few during the course of the day and I saw one burst in the air. I have been told that one struck and killed two of the horses in one of the carriages that was sent to the station for our party. As Dr. Ryan stayed to lunch with me at the hotel the rumor reached the hospital that we had been in this carriage and had been killed. The people at the hospital were much relieved, of course, to learn that such was not the case. Dr. Ryan has the best hospital building in Serbia. . . . We all have every reason to be proud of the way this hospital is run and of all Dr. Ryan's good work there, particularly admiring his remaining here after having had typhus fever and again taking up his work.

May 14th. Kragujevac. . . . We then went to see Mrs. Stovarts' field hospital. This is in tents and is situated on the outskirts of the town. As it had been raining for three days and most of the tents had no floors, only a thick piece of canvas serving as a floor in some of them, you can imagine the camp was in a very muddy condition. Mrs. Stovarts received us in rubber boots and trousers. She apologized for being without her skirt. All her assistants are women

doctors and nurses. The rest of the day was spent in inspecting Serbian hospitals. One of these had 1000 beds for typhus.

May 29th. Skoplje. . . . Yesterday I spent on an inspection trip to Velez and Stip. I went by train from here to Velez, taking the motor on the train with me, and from Velez motoring to Stip in a little over two hours. . . . I have no doctor available to send to Stip at the present time but will send one as soon as new doctors arrive. I reached Velez a little after two in the afternoon and the chauffeur ran the car out on the edge of the town where I had lunch, consisting of a tin of sardines and some crackers. It was the first I had eaten that day because I left too early to get breakfast. . . . Although I have no doctor to send to either Velez or Stip, I am trying to make as many inspection trips as possible before my new men come, in order to know just where to place them. . . . The disinfecting plant made from railway wagons has arrived, and I have found a desirable place to put it. This afternoon we shall bathe the people and disinfect their clothes at the same time. I am going to erect two large tents now, one for them to undress in and the other for them to dress in. . . . A thorough disinfection of hospitals is being carried out in another part of the town, and at the dispensary a large number of women, children and men are being attended. I think I told you that hitherto no provision has been made for the treatment of women and children, as all the doctors have been employed for the army. . . .

May 30th. Nish. . . . In my notes of yesterday I told you I was going to put up a tent for the men to undress in before bathing. . . . It was something of a feat to put up such a large tent, but with the assistance of Mr. Brink, who is very capable in field work, it was done.

The men undressed in the tent as we planned, passed in a line carrying their clothes to the steam sterilizing car and then to the shower baths. From the shower baths they passed to another car where they were sprayed with petroleum and received their sterilized clothes. Of course, it is needless to say that many of them were infested with lice. The clipping of the hair will be a regular proceeding hereafter. Some of the men said that they had not had a bath for over ten months. They seemed glad to be able to bathe, and some of the Austrian prisoners also asked to be allowed to bathe. This, of course, they were allowed to do after the Serbian soldiers had been looked after.

June 4th. Nish. . . . I met yesterday two women whose work I admire very much, one an American, Miss Simmons, from the Roosevelt Hospital in New York, and the other Miss Sandes, an English nurse. These women have been doing perfectly splendid work here in Serbia at Valuejo. Both of them had typhus there, but insisted in going on with their work afterwards. . . .

The following extracts were from a letter of Dr. Strong's to Miss Mabel Boardman of the Red Cross. It will be published in the "Red Cross Magazine" and should be read in full. The letter describes Dr. Strong's visit to several towns in Montenegro. Miss Boardman has kindly authorized this brief extract.

"My party consisted of Mr. Brink, Sanitary Inspector, a Serbian gendarme and my interpreter. We rode into Pech at 5.00 a. m., having been in the saddle or on foot for fourteen hours. My gendarme made a sorry appearance as we rode in to the village. It had rained all night and we were drenched. By half past six we had found and gotten up the doctor, and I went immediately to inspect the hospital. Here I found conditions in a dreadful and very alarming state. On entering the hospital I saw in the first room through which we had to pass, many piles of clothing which had been removed from the typhus cases. These lay on the floor and crawling over these and upon the floor in the vicinity were literally thousands of lice. I had never seen so many before—even in Serbia.

The hospital had about 250 cases of typhus. They were all badly neglected. The wards themselves were in a dreadful condition. There were no disinfectants and no means of bathing the patients, and no clean clothes or bedding for them. The condition of the latrines was beyond description. Unless strenuous measures are immediately taken here typhus will probably rapidly spread and another general epidemic result as happened in Serbia. I have arranged to disinfect the hospitals here, the patients and their clothes.

We shall place the troops that are now in barracks in tents while we are disinfecting their former quarters, clothes and bedding. I have also supplied clean clothing and night shirts for all the patients in the hospital and have quarantined Pech."

RICHARD P. STRONG.

BOSTON PARK SHOWS.

Boston, July 28, 1915.

Mr. Editor: A new educational method has been introduced with success this summer in Boston. The problem of how to reach a large number of the population who seldom read, if they read at all, has been met with considerable success by what may be called "teaching for fun."

A committee was formed composed of representatives of the Anti-Tuberculosis Society, the Boston Y. M. C. A. and Y. M. C. U., the Women's Municipal League, the Massachusetts Child Labor Committee, the Milk and Baby Hygiene Association, the Massachusetts Society for the Prevention of Cruelty to Animals, and the Foster Campaign Committee of the Associated Charities. These societies, united by their common interest in civic betterment and public health, co-operated in organizing and supporting the following plan: each society subscribed \$25 and guaranteed another \$25, if necessary, to meet the expenses. An active executive committee was formed, and a program of moving picture shows, with phonographic music, was laid out. The show was to be given five evenings in each week for a period of six weeks or more in the pleasure parks in different parts of the city.

A program committee obtained interesting pictures and selected moving picture films which were hired, and the program was varied each night. The committee secured the co-operation of some of the city departments, such as the Park Commission, and from private firms obtained the use of a phonograph and records, as well as an automobile truck to transport the whole show. It was necessary to hire an operator and a manager who obtained the necessary permissions and who saw that everything was ready and in place and all immediate arrangements made. The program was carefully arranged to give entertainment, and every third or fourth film or picture was educational.

It was estimated that during the first ten nights 60,000 people saw these shows, which began at 8.15 P.M. and lasted about two hours. Most of the people remained to see the entire performance and showed great enthusiasm at certain pictures, such as the weighing of a baby at a milk station.

The possibilities of public education appear to be very great through this form of entertainment. Since ignorance of hygiene and public health matters is one of the greatest difficulties which the physician meets today, we commend this form of education to the attention of the medical profession.

Very truly yours,

A. B. EMMONS, 2d, M.D.

SOCIETY NOTICE.

NEW YORK AND NEW ENGLAND ASSOCIATION RAILWAY SURGEONS.—The twenty-fifth annual session of the New York and New England Association Railway Surgeons, celebrating the quarter century anniversary of the organization of the association, will be held at Hotel Astor, New York City, October 21, 1915, under the presidency of Dr. W. H. Marey, of Buffalo, N. Y.

A very interesting and attractive program has been arranged. Railway surgeons, attorneys and officials, and all members of the medical profession are cordially invited to attend.

GEORGE CHAFFEE, M.D., Corresponding Secretary,
338 47th Street, Brooklyn, N. Y.

APPOINTMENTS.

BOSTON STATE HOSPITAL.—Dr. E. H. Cohoon has been appointed by the Boston State Hospital Trustees as administrator of the Psychopathic Hospital. For the past eight years he has been connected with the Rhode Island State Hospital.

COLUMBIA UNIVERSITY.—Dr. Fredrick Tilney, of Brooklyn, has been appointed professor of neurology at the New York College of Physicians and Surgeons, in succession to Dr. M. Allen Starr, who recently resigned.

MCGILL UNIVERSITY.—The following recent appointments are announced in the medical faculty. Assistant professor of chemistry, Dr. F. W. Skirrow; assistant professor of physiology, Dr. J. A. Gray; associate professor in pathology, Dr. Horst Gertel; assistant lecturer in physiology, Dr. T. P. Shaw; lecturers in immunology, Drs. J. C. Meakins and Fraser B. Gurd; lecturer in hygiene, Dr. R. St. J. Macdonald; lecturer in biology, Dr. F. S. Jackson, and associate professor of physics, Dr. L. V. King.

RECENT DEATHS.

DR. HENRY K. EWING, who died on July 30 at East Bridgewater, Mass., was born at Bentonport, Iowa, in 1839. For several years he had been in practice at East Bridgewater and was resident physician at the Millet Sanatorium. He is survived by his widow and by one daughter.

DR. DAVID STRETT, who died on July 30 at Baltimore, was born in Hartford County, Md., in 1854. After obtaining his preliminary education at Bethel Academy he received the degree of M.D. from the Baltimore College of Physicians and Surgeons. For the past thirty-five years he had been dean of the latter institution and professor of the principles and practice of medicine at the University of Maryland Medical School. He was formerly a trustee of the Baltimore Medical College and of the Maryland General Hospital and president of the Baltimore Medical and Surgical Society.

THE PRESENT STATUS OF THE ANTI-TUBERCULOSIS WORK IN NEW HAMPSHIRE AND SOME SUGGESTIONS FOR THE FUTURE.*

By ROBERT B. KERR, M.D., CONCORD, N. H.

Physician in Charge, Pembroke Sanatorium; Chairman of Committee Appointed by the New Hampshire Medical Society to investigate the extent of Tuberculosis in New Hampshire and make recommendations for legislative relief.

1.

THE TUBERCULOSIS PROBLEM IN NEW HAMPSHIRE.

(1) Tuberculosis is the most prevalent disease in New Hampshire and at the same time one of the most preventable.

(2) It causes more than 38% of all the deaths between the ages of 20 and 30 in New Hampshire.

(3) A conservative estimate places the economic loss to our state from tuberculosis as close on to a million dollars a year.

(4) (a) Eighty-four per cent. of all the deaths from tuberculosis in New Hampshire occur in the southern and central counties.

(b) More than one-half of all the deaths from tuberculosis in New Hampshire occur in Hillsborough and Merrimac counties.

(c) More than one-third of all the deaths from tuberculosis in New Hampshire occur in Manchester, Nashua and Concord.

(d) More than one-fifth of all the deaths in New Hampshire from tuberculosis occur in Manchester.

The great prevalence of tuberculosis in these sections of the state is due in part to the fact that more than two-thirds of the population of the state lies below Concord and also because of the overcrowding due to the large manufacturing industries. It is in the large, and even to a surprising degree in the small manufacturing districts, that we find the Great White Plague claiming its largest number of victims.

(5) Up to May, 1914, there were close on to 2000 active cases reported to the state board of health. In estimating the probable number of cases of tuberculosis in a given territory some authorities, taking 20 as a factor, multiply the number of deaths by that, and so figure the number of cases. More conservative authorities, particularly Philip of Edinburgh, use 10 as a factor. This figure was used as a factor by the Massachusetts Legislative Tuberculosis Commission in figuring the number of cases of tuberculosis in Massachusetts. Taking 10 as a factor and multiplying the number of deaths from tuberculosis in 1911 in New Hampshire by that, we have a little over 5000 cases of tuberculosis in our state.

(6) The State Board of Vital Statistics reports a marked decrease in the mortality from tuberculosis in this State.

The New Hampshire State Board of Health in commenting upon this urges the establishment of

* Read in symposium on Tuberculosis, before the Merrimack County Medical Society, April 13, 1915.

sanatoria to maintain this decrease, believing that "this reduction has taken place among the so-called better classes, or in other words, among the more prosperous, and perhaps more intelligent part of the community. It is these people who are more informed and who pay more attention to sanitary progress, and who, moreover, have the means at their command to enable them to do so. To reduce tuberculosis to its lowest terms sanatoria become a necessity.

(7) Tuberculosis is very largely a disease of the poor in New Hampshire, particularly among the shoe-shop and mill operative part of the population. The housewives and housekeepers are also very prone to this disease. The spread of this disease has been proven to be largely a matter of family contagion in the over-crowded unsanitary homes of the very poor.

2.

OUR AIM IN THE CAMPAIGN AGAINST TUBERCULOSIS.

The aim in the campaign against tuberculosis is the *control* and ultimate *suppression of the disease*. All over the world and the United States a vigorous campaign is under way to accomplish this end. To control and suppress tuberculosis requires:—

- (1) Control of the tuberculous.
- (2) Prevention of new cases.
- (3) Education of the people.

1. *Control of the Tuberculous.* A comprehensive plan for the control and suppression of tuberculosis must reach every consumptive in every stage of the disease and provide proper supervision in a sanatorium, hospital, or the home. This is our ultimate aim: only in so far as we accomplish this shall we stamp out this disease. It is not enough to care for a few consumptives,—we must reach all or necessarily while we are caring for the few the great number of unsupervised ones will spread the infection. Every consumptive must be rendered innocuous—only as we do this will tuberculosis be eradicated from New Hampshire. The consumptive is the source of the infection. Any reasonable and comprehensive plan for the suppression of the disease must begin with him.

The time is not far distant when every uncared for, unsupervised consumptive will be regarded as a disgrace to the medical profession as well as to the community at large.

When we realize that there are 4000-5000 cases in the state we can see the magnitude of the problem and the immense amount of work which must be done to accomplish the fulfillment of our ultimate aim. However, this should cause no one to assume a do-nothing attitude, but rather spur us on to do our share, utilizing every proper agency at hand for the eradication of the Great White Plague. It can, must and will be accomplished. Pasteur has said that it is in the power of man to cause all germ diseases to disappear from the face of the earth. There is

no reason why tuberculosis cannot be controlled and suppressed just the same as we control and suppress other germ diseases.

In studying the development of the anti-tuberculosis work we find certain definite stages in the tuberculosis movement. The first stage we find to be the establishment by states of sanatoria for the treatment of favorable cases. These were concerned mainly with the cure of "cases." Soon after it was realized that the advanced cases were a greater menace and a greater burden to the state, and the conclusion was reached that in the proper care of these cases the safety of the public health of the community would be most largely secured.

So we have the second stage of the tuberculosis movement. This stage has been characterized by a vigorous movement for the establishment of local and county institutions for the care of advanced toxic cases. New York has made plans for the establishment of hospitals for these cases by every county, in spite of the fact that it has a considerable number of institutions scattered all over the state.

Massachusetts, although it has four large state sanatoria, has passed a law requiring the establishment of hospitals for advanced consumptives by cities of 10,000 inhabitants or over.

We are at the present time in the midst of this important stage of development of the forces in combat against tuberculosis.

The third stage of development and the one which is the connecting link in our campaign, is the movement for the establishment of dispensaries with their great possibilities of early diagnosis and their corps of nurses for home supervision of cases that have returned from sanatoria and of patients who will not go to a sanatorium. Through the tuberculosis dispensary nurses or a state-wide system of visiting tuberculosis nurses we can provide in any corner of the state, however remote, free medical supervision for every indigent consumptive and his family. In this way we can hope to reach every consumptive, and only as we accomplish this shall we get the best results in our campaign.

The efficiency of this system lies in the close relationship between the dispensary-sanatorium and hospital, so that every indigent consumptive in the state and his family cannot only receive treatment at home in the home, but sanatorium and hospital treatment as well; and what is quite as important, is followed up and kept under observation or treatment upon his discharge from the sanatorium or hospital.

Supervision of all consumptives means the expenditure of a vast amount of hard earned work; large amounts of money; enlargement of our present institutions; establishment of new local institutions in those parts of the state where most needed for the advanced unfavorable cases; and a comprehensive scheme of home supervision.

To do all this *now* would in the end be economy. If we fail of this aim, we shall not do our

full duty in the war against the Great White Plague.

2. *The second important feature is the prevention of new cases.* We must stop manufacturing consumptives or else we shall have new and larger crops to deal with in the coming years. To this end in the first place we must isolate the foci of infection; second, we must remove those conditions which tend to foster and breed tuberculosis. We must do away with the 'lung blocks'—the overcrowded unsanitary homes of the poor. We must make working conditions sanitary. We must prevent overwork. Child labor must be suppressed and woman labor restricted. We must raise the standard of living by paying reasonable wages for reasonable hours of labor.

3. *The third important factor is the education of the people in right living and in the prevention of tuberculosis.*

The people must be taught the lesson of personal hygiene,—that drunkenness is not only the curse of the home but the curse of the body as well, and a most active ally of the tubercle bacillus.

The public must be educated to seek the doctor early when suspicious symptoms present themselves. They must be made to appreciate that the tubercular member of the family, for his own sake as well as theirs, must be sent to the sanatorium or hospital.

They must be taught the need of examination of other members of the family exposed to the infection, so that, if it is found necessary, the disease may be treated in its incipency.

They must be educated so that they will be willing to send the tubercular child away for treatment, and not as now, let unreasoning paternal love stand in the way, preferring a dead child in the home to a live one in the sanatorium.

I know of no better way to accomplish all this than by a good system of visiting nurses. The District Nursing Associations in Concord and Manchester are of great value in this particular direction.

3.

THE FORCES AT WORK AND THEIR EQUIPMENT.

1. *Laws relating to the prevention of tuberculosis in New Hampshire.*

We have our registration law, requiring the registration at the State Board of Health of every known or suspected case of tuberculosis. We have our anti-spitting laws. We have a law requiring that every death or removal of a consumptive be reported to the board of health and the premises fumigated.

2. *Institutions.*

(a) We have our excellent State Sanatorium at Glenduff, New Hampshire, located high in the

mountains, designed primarily for the treatment of favorable cases. It has a well equipped plant and has beds for sixty patients. It has done and is doing splendid service in saving the lives of many consumptives. It plans to reject all unfavorable advanced cases, but has accepted many moderately advanced cases because there were not enough applications of incipient cases to fill it to its capacity. This is true of the majority of institutions for incipient cases. It is unfortunate that far too many consumptives are not diagnosed until they become moderately advanced. The only question for admission is not whether the case is incipient or advanced, but whether the patient offers a reasonable prospect of improvement or cure. It does admit advanced cases when they present such a reasonable prospect of improvement or cure.

(b) Under the provisions of a bill passed in 1911 and 1913, which appropriated \$20,000 a year for two years in 1911 and in 1913 appropriated \$15,000 a year for two years, a large number of advanced cases have been cared for at the Pembroke Sanatorium and the Tuberculosis Ward at the Hillsborough County Hospital at Grasmere. About twenty-six state patients can be cared for at any one time under this appropriation. The Tuberculosis Committee of the New Hampshire Medical Society prepared two bills, making provision for advanced consumptives for presentation to this present legislature; one provided for the establishment of a state hospital sanatorium, to be located near the centers of population and designed for the treatment of advanced cases; the other asked for an appropriation of \$50,000 a year for two years for the treatment of these cases.

We were advised by the powers that be that the first bill would be absolutely killed because of the poor condition of the state's finances. The second bill had many advantages and had two objects in view: First, to provide treatment for a goodly number of the state's unfavorable advanced cases; second, to stimulate the establishment of local institutions by charitable people in parts of the state where such institutions were most needed.

This latter bill has passed the House, with the amount of the appropriation asked for cut to \$17,500 a year for two years.* We were told that there was no question of the need of the work or of the merits of the bill, but the state had to cut down on its appropriations.

If the whole amount asked for had been appropriated, both objects of this bill would have been secured. It is easily seen that besides only providing treatment for about thirty-two advanced cases at any one time, it will not encourage the establishment of new local hospitals for advanced cases. No one institution hoped or expected to be able to care for enough patients to use up the \$50,000 a year—the idea was to secure provision for the large number of ad-

* The Senate has since increased the appropriation to \$20,000 a year—the House has concurred and the bill signed by the Governor.

vanced cases in urgent need of treatment and at the same time encourage the establishment of new local institutions so that the unfavorable cases might be cared for near their homes and family. Thus the patient could be frequently seen by his family, get the necessary nursing care, and a focus of infection be removed from the home.

3. Organizations.

The State Board of Health, the New Hampshire Red Cross Society, the tuberculosis committee of the Concord Charity Organization Society, and other organizations, are doing considerable work in educating the public. The New Hampshire Red Cross Society and the New Hampshire Federation of Women's Clubs have contributed funds for the treatment of patients at Glendiff and Pembroke. The district nursing associations and school nurses are doing excellent work in supervising cases in the homes and providing examinations for individuals presenting suspicious symptoms. In this way, especially in Concord, a number of early cases undoubtedly due to family contagion, have been brought to light.

4.

EQUIPMENT WHICH IS LACKING.

1. Laws.

A valuable addition to our equipment would be the enactment of a law empowering the State Board of Health or local boards of health to remove to a sanatorium or hospital a consumptive whom they deemed dangerous to the public health, either through inability to secure proper preventive measures at home or through carelessness or indifference on the part of the patient in regard to the prevention of spread of his infection.

2. Earlier Diagnosis.

Of great value would be a campaign for early diagnosis throughout the state so that our State Sanatorium may receive a larger percentage of favorable cases and so save more lives to the state. As the possibility of cure or arrest of this disease depends largely upon the extent of the disease in the lungs, it is of vital importance that the consumptive be caught in the incipient stages. It is the duty of the conscientious physician to do so.

3. We lack adequate provision for the treatment and care of the unfavorable, advanced consumptive.

Of vital importance are adequate funds and local hospitals for the treatment of these cases. In both of these, New Hampshire is pitifully lacking. More beds for this class of cases is an imperative need. More local institutions are an absolute necessity if we hope to cope with this infection. The bill presented to this legislature had both of these objects in view.

There should be at least 60, and preferably

100, beds in New Hampshire for advanced unfavorable cases of tuberculosis.

We had a splendid hearing upon the bill have spoken of before the Appropriations Committee of the House. Twenty-six prominent people of the state, among them fourteen physicians, the overseer of the poor of Manchester, the superintendent of the District Nursing Association of Concord, the city missionary of Manchester, the secretary of the State Federation of Labor, the secretary of the State Conference of Charities, and others interested in the humanitarian work of the state, testified to the great need.

The doctors responded well to a call for their aid, and, as I have said, fourteen appeared before the hearing, among them the president and secretary of the State Medical Society, the secretary of the State Board of Health, and the chairman of the Legislative Committee of the State Medical Society.

The result was that the committee was impressed with the great need of the work, and the chairman told us at that time that there was no question of the need of the work or the merits of the bill and that the committee would do all it could, but the financial resources of the state would not permit granting of the full appropriation. It is unfortunate indeed that the committee did not make larger provision for these cases.

4. *There is practically nothing being done for the tubercular children of New Hampshire* There are no sanatorium beds for tubercular children. There are no open schools. This places a big handicap upon the medical inspectors in schools. If we wish to save the anemic, predisposed, and incipient and closed tubercular children of today from becoming the active cases of tuberculosis in the future, open air schools and home supervision are a necessity. In many instances this could be done without great expense—a room or a number of rooms with all the windows out being utilized for the purpose. There is no provision for the treatment and care of the indigent crippled tubercular children of New Hampshire.

5. *We lack a comprehensive scheme of home supervision.* In a few instances this is being done well by the district nursing associations particularly in Concord, but much more work is necessary in this direction. This would involve a considerable amount of education and mean a good staff of visiting nurses. The state would get full value for every dollar expended. This could be done under the supervision of the State Board of Health or a State Tuberculosis Commission or some other state body. It would be perfectly feasible to cover the state with visiting nurses for the purpose of discovering and providing adequate care for practically every case of tuberculosis in the state. You will find that no matter how adequate the sanatorium and hospital provision, there are many who will not and cannot go to such institutions. Home treat-

ment is not to be recommended unless it provides the most careful home supervision, together with adequate relief and medical attendance. This, in conjunction with sanatorium and hospital treatment, would be of great value in getting every case under control. This is the ultimate aim which we must keep constantly in view.

Until every case is under control the sources of the infection are unguarded, and the disease will spread quietly, slowly, but surely.

6. *We lack a central organization to direct the tuberculosis work in New Hampshire.*

A central board or commission could direct the forces at work,—supervise sanatorium and hospital treatment, prevent overlapping, initiate and extend home supervision, stimulate the public as to the necessity of dispensaries, open-air schools, etc. Such a commission, thoroughly conversant with the various problems of the work, knowing the particular needs of the forces at work, could appear before our legislative committees, and, with the authority of a state organization, tell them the needs and ask for the necessary equipment. *It is a disgrace to New Hampshire that previous to this last legislature a few physicians, social workers, and others interested in humanity, should have had to fight for what little provision had been made for the unfortunate dying consumptive.*

Between Dr. Wise, the superintendent at Glend Cliff, and myself, there has always been a cordial feeling of coöperation. We have met occasionally to discuss the problems confronting us in our work, with much benefit to myself. We both feel that a central tuberculosis board would be of distinct value in making more effective the tuberculosis work in New Hampshire.

5.

SOME SUGGESTIONS FOR THE FUTURE.

1. *A Campaign for Early Diagnosis.* As the physician is the only one who can make the diagnosis we must urge upon the profession the great need of care and attention to earlier diagnosis; and at the same time the public must be instructed as to the vital importance of consulting the physician when suspicious symptoms present themselves.

I would suggest that a paper be read upon the subject of tuberculosis, preferably early diagnosis, before each and every county and local medical society. I see no reason why so vital and important a subject as tuberculosis, with its tremendous influence upon the public health, should not be freely discussed before these societies at least once a year. Certainly a paper should be read upon this subject at annual meetings of the State Medical Society.

I would suggest that all the members of a family in which a case of tuberculosis exists be examined. In this way many cases may be discovered due to family contagion. To accomplish this means tuberculosis dispensaries, particu-

larly in the cities. The establishment of such dispensaries would be of great value in discovering early cases and, of equal importance, keeping tabs on the cases returning home from the sanatoria. In some instances this work is being done by the District Nursing Associations.

2. *A Permanent Tuberculosis Committee of the New Hampshire Medical Society.* As tuberculosis is the most prevalent disease in New Hampshire and the physicians of the state must of necessity be interested in the problem, it would seem wise that a permanent tuberculosis committee of the State Medical Society be appointed to consider matters of interest in regard to tuberculosis and bring annually to the attention of the society any such matters of interest or matters of policy in the campaign against tuberculosis as may seem advisable to them. Such committee may confer with the Legislative Committee of the State Medical Society and may with them prepare any bills deemed advisable.

In this way the members of the society may be kept in touch with the various aspects of the tuberculosis problem and may add their influence and help towards their proper working out and solution.

3. *A Vigorous Campaign for Proper Provision for Care of the Advanced Case.*

As the provision made for the treatment and care of these cases is wholly inadequate to the need, a vigorous campaign for proper provision for the care of these cases is essential. This is not a question of the survival of any institution, but a question involving the safety of the public health. These cases must be provided for; for the sake of humanity, for the protection of the public health. It is a question which cannot be dodged or evaded. The advanced dying consumptive must be provided for. This must be done in a humane way, humane to himself and to his family, *i. e.* in local institutions within easy reach of his relatives and friends.

A good large state hospital for the treatment and care of unfavorable, advanced cases located near the centers of population is an absolute and vital necessity. If the state cannot do this then it should pass a large enough appropriation to care for those in urgent need of treatment, in this way providing for the consumptive, and at the same time encouraging the establishment of local institutions for his care. This latter policy is the one recommended by the National Association as being the most economical and satisfactory one for the state to pursue. Only when we have such local hospitals, where the advanced unfavorable case can be isolated, the same as our cases of scarlet fever and diphtheria, shall we control tuberculosis. *The control of tuberculosis is largely a question of control of the tuberculosis.* Give the favorable case every chance for cure or arrest of his disease, and educate and isolate the unfavorable, advanced consumptive in a local hospital or sanatorium. If we tackle the problem as it should be tackled, making the

fighting forces and their equipment commensurate with the size and importance of the enemy, we shall soon secure success in our efforts. If the provision is small, the day of victory is farther off, and the fight in the present all the harder and less encouraging. We, as physicians, should exert every legitimate influence at the next legislature to obtain adequate provision for these cases.

4. *Open-Air Schools.*

Of great value in the campaign would be the establishment of open-air schools in our cities. They are a necessity—not a luxury. Some facilities of this nature are necessary in Manchester, Nashua, Concord, and without doubt, some of the other larger cities.

5. *Provision for Crippled Tubercular Children.*

It is a disgrace to New Hampshire that there is no provision in the state for the treatment of crippled tubercular children. There should be such provision, and it could be gotten if the New Hampshire Medical Society and the people of New Hampshire made a vigorous campaign to secure it.

6. *Home Supervision.*

A comprehensive plan of home supervision, particularly in those cases unwilling to go to a sanatorium or hospital, would be a great help in the campaign.

7. *A Central Tuberculosis Commission or some state body, to direct the forces at work, carry out and extend home supervision, etc.,* is a necessity and we should make a vigorous effort to secure it.

I am aware of the fact that there are many problems which must be worked out in our campaign. The coming years may show that our present methods are crude and incomplete, but I believe we are working along the right lines. The attainment of the full aim in our campaign, *i.e.* the control and ultimate suppression of tuberculosis, means years of hard, persistent and perhaps, at the time, unappreciated work. It is apparent that the carrying out of these suggestions, if deemed feasible by the society and backed by the people, means a great expenditure of human effort and thought, as well as the outlay of large sums of public money.

However, it will be worth it all if we can in time stamp out this plague of all plagues. Human life is the most precious possession of all, and in the conservation of it dollars and cents must not be considered.

The time has gone by when we can place the blame on the Almighty for carrying off 200,000 of the people of the United States every year with consumption in the very prime of life. The Lord intended every one to live his allotted three score and ten. The Almighty sends tuberculosis to no man. It is man that passes it on to man. It is our duty and it is within our power to stamp out this disease—destroy this destroyer of the home, health, and happiness.

If the great danger and need were persistently and forcibly brought home to our people and our legislators I cannot but believe that the necessary equipment would be given. New Hampshire is not a rich state, but it can do its proportionate share and is willing to if its people and legislators can be convinced that we, as physicians, are in earnest in our campaign against the Great White Plague.

THE PRACTICAL TREATMENT OF INEBRIETY IN A STATE INSTITUTION.*

BY IRWIN H. NEFF, M.D., NORFOLK, MASS.,

Superintendent, Norfolk State Hospital, Norfolk, Mass.

PREAMBLE.

THE futility of fine and prison sentence for habitual drunkenness is now generally recognized; the public, realizing the economic loss to the state from such measures, is becoming more insistent in the demand for the inauguration of some plan which will satisfactorily care for the increasing number of cases of drunkenness which are constantly appearing in our courts, or which voluntarily solicit treatment.

Any plan proposed for the care of such cases should recognize the characteristics and personality of the inebriate and consequently the need of distinctive care for such individuals. The modern treatment of inebriety demands the initiation of a widespread policy, a policy which must be sufficiently elastic to permit of its universal adoption.

The inebriate, dependent on the degree and intensity of the condition, demands a specialized treatment, which may be tentatively divided into two methods, namely, remedial and custodial. The employment of the first method demands minimum institution treatment and maximum out-patient care. The enactment of a plan for custodial care requires more prolonged institutional detention. Prior to the selection of the treatment for these two distinctive types, an accurate differentiation of the cases must be made. This diagnosis or individualization should be relegated to those who have specialized in the work.

Contrary to the general opinion, a well equipped hospital for the inebriate is so built and regulated that adequate provision is made for the care of the varied types. The requisites of such a hospital are now well recognized. The state care, which requires for its success a well defined plan, must include, first, a parent institution; second, a well organized out-patient department which must allow for extension as conditions demand; third, detention hospitals

* Read at the National Conference of Charities and Corrections, Baltimore, Maryland, May 14, 1915.

in metropolitan centers, which will care for cases of delirium tremens, alcoholic psychoses, and those suffering from acute alcoholic diseases. The success of state care depends on the co-operation of these interests to their fullest extent.

Much of the ill success of institutional treatment for habitual drunkenness is due to failure to recognize that the inebriate is a distinctive individual and that in order appropriately to care for him it is essential that an institution be built for him with specialized features.

The treatment and care of the habitual drunkard, as above outlined, can be adequately met by the state, which, by assuming such control, is providing a charity as clearly a duty to the community as caring for the insane, epileptic and feeble-minded. Certainly the benefits resulting from such care prove its economic importance.

Any state inaugurating a plan for the care of the habitual drunkard should realize that the prevention and cure of drunkenness can come only by education. An institution established for such a purpose should be considered as a general educational center for the education of the public concerning the evils of alcoholism.

INTRODUCTORY.

During the past five years two commissions have been appointed in the Commonwealth of Massachusetts to investigate the subject of drunkenness, and the best means of correcting and controlling that evil. The economic loss to the state on account of drunkenness was the appealing argument for the creation of these commissions, an argument which could not with justice to the citizens of the state be disregarded. The reports of the respective commissions called attention to the uselessness of sentencing habitual drunkards to penal institutions, declared this custom wrong in principle and recommended its abandonment in most instances as soon as other suitable provisions could be made for the care and treatment of confirmed drunkards. Although the subject matter of the reports is largely descriptive of existing conditions in Massachusetts, it is believed that conditions analogous must exist in other states. It is not unreasonable to suppose that the plan for caring for the habitual drunkard or inebriate, sanctioned by Massachusetts, might prove satisfactory if adopted by other states. The policy, which will be described, is sufficiently elastic so that its inauguration by any state would be feasible; the real economic importance of the plan is certainly indisputable. Thus far its benefits to humanity have proved its worth.

THE INEBRIATE.

A recognition of the need of discriminative care of the inebriate necessarily implies the acceptance of the modern conception of the condition. The failure of the public to recognize the true nature of inebriety and the procrasti-

nation of those who have had it in their power to inaugurate and direct reforms or remedial movements have heretofore proved serious handicaps to the carrying out of any practical plan which could satisfactorily individualize and treat these dependents. Such ignorance or heedlessness has in great part been responsible for the many irregular methods which have been advanced and heralded as cures for drunkenness and allied conditions; therefore, as an essential foreword to the subject of my paper, I will define inebriety. Before we can successfully cope with a disease it is necessary that we know the nature of the malady; a parallelism can be found in inebriety. Unless we can appreciate its characteristics and peculiarities we cannot hope to combat it. For a proper understanding, the study of a condition or a disease must necessarily begin by studying the environment and the individual responsible for the state or disturbance. The study of inebriety is no exception to this rule. A knowledge of the personality of the inebriate must be the foundation stone for the treatment or for any suggestion made to the public for the control of drunkenness. It has always seemed to me that much of the misunderstanding about inebriety may be traced to our misconception of the word "inebriate." An inebriate, medically speaking, is an habitual drinker or an habitual user of drugs or some other form of intoxicants. All cases of intoxication are not cases of inebriety, but all confirmed or habitual drunkards are properly classed as inebriates. Inebriety has been called a disease. This has been vigorously opposed by those who would have us consider it a habit requiring only correctional measures for its control. Adherents to the "habit" theory have contended that any existing diseased condition, whether mental or physical, is due to wilful indulgence.

Again it is maintained by some of those who are willing to consider inebriety tentatively as a disease that a general acceptance of this understanding would severely operate against any plan proposed for the suppression of drunkenness, as it would eventually lead to the public belief that the inebriate is irresponsible. I have also found that many persons have preconceived ideas about the habit of drunkenness, their opinion being formed either from the observation of a single case or from conclusions arrived at by a wrong interpretation of the types. It seems unnecessary to say that the study of drunkenness is to be approached with a realization that such a study has apparently many complex features, the complexity disappearing when we appreciate the importance of the personal equation. Although all classifications of drunkenness are indefinite and have overlapping features, it is possible for an experienced person to make a workable classification which can be of material aid to him in determining the value which might come of appropriate treatment. I feel quite sure that considerable time and energy

are in many cases misspent in expecting brilliant results from treatment of cases where the nature of the inebriate condition precluded recovery, or indeed any material improvement. The study of drunkenness is a medical-social study and for the successful application of any method advanced for its control it is essential that we appreciate that, although the diagnosis and treatment depend on the adjustment of the medical and social findings, the line of demarcation between these two studies is closely defined. Our studies of the personality or make-up of the inebriate have been for the most part a verification of the conclusions so clearly and tersely given by R. W. Branthwaite in his Report of the Inspector under the Inebriates Acts for the year 1912. It must be remembered that these conclusions do not refer to accidental or occasional drunkenness which is wilful or premeditated, and not related to inebriate alcoholism. These states of intoxication for our present purposes may be entirely disregarded. Branthwaite's description of the inebriate, which I quote *verbatim*, is as follows:—

"An inebriate is a man who may or may not desire to live soberly, but in any case cannot, unless or until some change takes place in his physical or mental state. The more we see of habitual drunkards the more we are convinced that the real condition to be studied, the trouble we have to fight, and the source of all the mischief, is a psycho-neurotic peculiarity of some sort; an inherent defect in mechanism, generally congenital, sometimes more or less acquired. Alcohol, far from being the chief cause of inebriety, is merely the medium which brings into prominence certain defects that might have remained hidden but for its exposing or developing influence."

The writer, for one, does not believe that any single inebriate, of all the many thousands admitted to retreats and reformatories, has voluntarily and of intention brought himself to that state. On the contrary he is convinced that all who possess the power to appreciate the seriousness of their condition have urgently and honestly desired to live a sober life, and have fought to this end and failed in a struggle against forces, the strength of which a normal man is incapable of realizing. Sufficient credit has never been given to the honesty of an inebriate's fight against inclination, or to the inherent weakness of his power to resist impulse that renders his struggle for victory unsuccessful. If this could be brought home to many people, who now have nothing but blame and abuse for the drunkard, there would be more sympathy shown—and sympathy would breed help. Who knows how many of the inebriates of today might have been saved had they dared to acknowledge their state during the early days of its development, and ask for help, without fear of penalty or ostracism.

The inebriate, then, is the subject of a peculiarity, the distinctive characteristic of which is his inability to take alcohol in moderation, de-

spite the most strenuous efforts of which he is capable. It is often possible for him to abstain from alcohol altogether, but rarely, if ever, possible for him to take it without becoming drunken. He is the victim of a psycho-neurotic fault that implies a defective power of resistance to the action of alcohol or drugs, in exactly the same sense as tubercular tendency implies impaired resistance to the specific infection of that disease. The peculiarity or fault is an extremely potent one, calling for recognition as the true inebriate state, of which drunkenness, disorder, and erratic behavior generally, are merely outward and visible signs.

Although it is clear that a marked correlation exists between the recognized forms of mental defect or disease on the one hand and habitual drunkenness on the other, the association is not definite enough to justify the commonly heard statement that all inebriates are more or less insane or mentally defective. When inebriates of all social grades are classed together it will be found that the majority are neither the one nor the other; indeed, many typical inebriates are extremely capable individuals during sober intervals. Notwithstanding this, even the most mentally sound amongst them are not normal persons; the evidences of peculiarity are too definite to be ignored, although its character is difficult to define, and its location obscure.

Concerning the mental characteristics and make-up of an inebriate, I can safely say that when analyzed many cases of habitual drunkenness show mental and physical defects which may, or may not, have antedated the drunkenness, a fact which lends additional support to the contention that the punitive measures which are habitually or quite generally used toward these individuals are unjust and should be discontinued. It is true that this type of case might consistently be considered hopeless or irresponsible. This is an added reason for condemning the sentencing of such individuals, a method which is irreconcilable with our findings. Statistical knowledge bearing on the subject is overwhelmingly supportive of the conclusion that a considerable number of confirmed or habitual drunkards are mentally defective, the defectivity being manifested in various ways, ranging from mild emotional disturbance and judgment perversion to well defined psychoses. While these mental defects have been quite generally found in the more confirmed or advanced cases, some recent investigations and analyses of incipient inebriates have shown certain functional nervous disturbances which might have antedated the drunkenness. Laboratory methods which are now being used for the study of these cases will doubtless in time give us valuable results; then, and not until then, can we definitely assert that actual mental defect in the drunkard existed prior to the development of the confirmed drunkenness. The results along these lines have been more than suggestive, but not entirely conclusive.

Recognizing that inebriety is a well defined condition, we can define the inebriate state as follows:—

(a) Inebriety is an expression of nervous weakness, the nervous weakness being inherited.—a psycho-neurotic fault; founded on this weakness, manifestly a defect, is a habit we call drunkenness.

(b) The inebriate is therefore the sum total of his personality or make-up, and the symptoms which we call drunkenness.

(c) Inebriety can be considered technically as a form of a disease in the sense above described, a condition which implies a graded responsibility, the degree of responsibility being determined after a consideration of the individual case.

THE INSTITUTION.

There is a popular belief that institutional care is all sufficient for those unfortunates who are mentally or physically diseased; especially has institutional care been recommended for those persons who are resistive to the ordinary methods usually employed for the care and treatment of chronic disease. Inebriety has been no exception to this rule; indeed, if one would review the history of the management of the drunkard he would doubtless be surprised to find that an appreciation of the chronicity of the condition has existed from the earliest times, and that this alone has been responsible for the demand for the segregation or imprisonment of the drunkard. This method of management, with little or no variation, has been handed down from generation to generation, and as no practical substitute has been offered, the time-honored system, punishment, or coercion, in some form, for the drunkard has been continued. I do not deny that many honest attempts, both preventive and remedial, have been advanced to solve the problem. These attempts, due largely to the failure to recognize that voluntary or coöperative methods are superior to enforced or punitive measures, have met with little success. We must remember that today we are better prepared to meet the problem. The knowledge that the inebriate is an entity and our understanding of the benefits from individual treatment, have given us valuable weapons to fight with, weapons which, if considerably used, are of considerable range and value.

Any plan which is put into practice for the treatment or amelioration of drunkenness should be controlled and administered by the state. The magnitude of the problem and the closely interwoven economic questions argue against local or municipal control.

The successful care and treatment of inebriety demands the inauguration of a definite policy which includes both institutional and non-institutional departments, both of these departments being inter-related. The institution, or founda-

tion head, of the system demands first consideration. On the threshold of our contemplated plan for the practical care of the habitual drunkard, it appeared to us that our work should be directed: first, to the extension of individual treatment of cases; second, to the securing of remunerative employment for cases which were under our care and treatment; third, to the compiling of accurate histories of those who had been discharged from the hospital; fourth, the establishment of after-care, which department should be an integral part of the hospital.

It is, therefore, at once apparent that something more than the mere housing of the individual is needed. An institution for the purpose must be adaptable; it must have distinctive qualities and be especially built and equipped for the class of persons for which it is intended; in other words, certain conditions are required, departures from the character of an ordinary institution; and lastly, the institution should be so constructed that it can adequately treat the varied types of inebriety committed to its care. The requisites of such an institution are:—

(a) A sufficient area of land to provide for agricultural development and for outside employment for the patients.

(b) Sufficient plant for industrial training.

(c) A tract of land of sufficient continuity so that there will be an opportunity for the segregation of the diverse cases.

(d) Adequate provision for both male and female inebriates.

Acting on these recommendations, a large tract of land was purchased in Massachusetts. The area selected has natural advantages; in other words, the land is largely undeveloped, thus allowing for considerable work for the inmates and affording an opportunity for affiliation and coöperation with the forestry, agricultural and other State Commissions. This coöperation in our estimation is an essential part of our educational scheme and is also of sufficient economic importance so that the economies have been helpful in building and equipping the plant. The acreage, over one thousand acres, is sufficiently large so that the requisites before mentioned have been met. The cottage or colony is the pivot centre of our scheme. Three different colonies are considered. First, a hospital colony for men, which will take care of the hopeful cases; second, a detention farm colony which will provide for the more chronic and resistive type of patients; third, a hospital for women. Briefly expressed, the colony groups would care for the following types of patients: The cottages for men would receive:—

1. Patients who come voluntarily or who are committed by the courts.

2. Young habitual drunkards placed on probation by the courts on condition that they spend a specified period at the hospital.

3. Suitable cases transferred on parole from the detention colony.

4. Non-criminal habitual drunkards committed by the criminal courts or received voluntarily as a condition of probation.

The cottages for women would receive:—

1. Patients who come voluntarily or who are committed upon application.

2. Cases placed on probation by the courts on condition that they spend a specified period at the hospital.

The cottages, which are units, are built in groups distributed over the large tract of land. A centralization of the administrative and service group is necessary. For purposes of economy these buildings, with the ordinary service buildings, form a central group. I would at this point emphasize that the essential part of our housing scheme is the cottage. These cottages must be so situated and constructed that they will readily lend themselves to the needs of the patient groups.

OUT-PATIENT DEPARTMENT.

At an early period in our institution career we recognized that the mere training of a patient at the hospital was in itself an inadequate provision, when a discharged patient was compelled immediately to return to adverse conditions. Accordingly, five years ago an out-patient department and clinic were developed. Modest in its beginnings, it has rapidly grown in extent and its usefulness has progressively increased. The Norfolk State Hospital has now established in metropolitan centers two such departments which are serving definite areas of the state. The department, which is in charge of a physician who is assisted by non-medical workers, is a fixed part of the hospital. An active vocational bureau is maintained, visits are made to the homes of discharged patients, aid is supplied to dependent families and every effort is made to reinstate the patient in his business interests and domestic relations, for unfortunately it is often the case that the victim of habitual drunkenness has lost not only his own self-respect, but has forfeited the respect of others. At this point a strong helping hand is needed. This was the fundamental reason for the beginning of our out-patient work. Another feature of the department is the medical and social clinical work. An increasing number of persons apply for advice, and it is quite often feasible to treat such persons outside of the institution, reserving the hospital or custodial treatment until conditions demand it. Furthermore, the out-patient department serves as a central educational focus, acquainting the public with the aims and purposes of the hospital. This department has rendered valuable aid in carrying out the educational and medico-social work begun at the hospital. Every patient at the time of his discharge is impressed with the idea of coöperating with the out-patient department. Some of these discharged men report to the hospital, others at the office of the

out-patient physician, while others are visited at intervals by the physician of the out-patient department. As before stated, particular attention is paid to the social readjustment of the patient, and every effort is made to secure for him congenial work and an environment suitable to his condition. During the past year 3286 visits have been made to the homes and workshops of discharged patients, and over one hundred permanent positions have been obtained for them. In order to emphasize the importance of the work of this department the following figures, covering one year's work, are given:—

Visits to office	471
Visits to hospital	105
Visits to homes of patients who are at the hospital	516
Visits to homes of patients who have been discharged from the hospital	2770
Visits to employers relative to work for discharged patients	130
Situations obtained for discharged patients ..	97
Men who are working and abstinent	1188
Men who are abstinent, but not working ..	227
Men who are drinking some, but working ..	295
Men who are drinking and not working ..	472
Men who have not been located	298
No answer to inquiries	481
Men applying at office, recommended for admission to hospital	470
Men applying at office, refused admission to hospital	367
Patients reporting at office, abstinent and working	360
Men drinking whose return was advised ..	137
Men drinking whose return was refused ..	184
Inquiries	473
Consultation with outside parties	76
Letters sent out relative to discharged patients	891

Another branch of the parent institution which should be considered is the establishment of hospital clinics or detention hospitals. It is not necessary that these hospitals should be especially built for the purpose, as arrangements can frequently be made to coöperate with general hospitals which are already established. In such branch hospitals should be treated cases of delirium tremens or cases of acute alcoholism, which either voluntarily present themselves for treatment or are brought in as emergency cases.

The plan as developed by Massachusetts, and which is now in part in active operation, can be described as follows: First, a state hospital for the treatment of alcoholic and drug habitués, developed on the colony plan, with a sufficiently ample and flexible equipment so that appropriate care and treatment can be given to the different types of inebriety; second, an out-patient department and clinic with broad and well-defined duties; third, detention hospitals and hospital clinics having specialized features for the care and treatment of cases of acute alcoholism.

A substantial start has been made. The Massachusetts central state institution has been in part built, out-patient departments have been established and the coöperation of the hospitals is assured. To the trustees and to those of us who are interested in the proposition the real incentive for the contribution of our work is our conviction that the public believe in the integrity and stability of the system as planned six years ago.

I feel that my paper would be incomplete if I failed to describe our method of treatment. Believing as we do, that the inebriate condition has for its basis a distorted mentalization, our efforts are directed in an endeavor to interest the patient in his individual case and, having accomplished this, to make the interest self-sustaining. Our experience has shown us that the success of hospital treatment depends upon:—

(a) The ability of the patient to coöperate in treatment.

(b) Our ability to introduce into the patient's mentality some tangible substitute for the desire for artificial stimulation.

Such a result is brought about by attention to the patient's mental and physical hygiene, and necessarily depends on the educational measures inaugurated at the hospital and continued by the patient after he leaves the institution. The treatment must necessarily be considered as in the realm of physiologic therapeutics, which is supplemented by the simplest form of suggestion. The suggestion is really an auto-suggestion, the result of a correlation of impressions which the patient receives from his association with the physicians and from his relation to the hospital environment. The physician is concerned in an analysis of the individual case, which is made possible by encouraging the patient to coöperate in his own recovery, by strengthening his self control.

I have reserved for my concluding paragraphs an account of our work extending over a period of five years. Considering the result of hospital treatment, it must be borne in mind that the total number of discharges is considered. No attempt has been made to differentiate cases. Each case has been considered individually, the following conditions determining the final report of the result of treatment.

1. The type of inebriety, divisible for practical purposes into three classes:—

(a) The regular drinker,—one accustomed to the use of stimulants daily.

(b) The irregular drinker,—one accustomed to the use of stimulants at short intervals.

(c) The periodical drinker,—one accustomed to drink at periodic intervals, periods of months or years elapsing between the periods of in-sobriety.

Thus a man whose period of drinking occurs at intervals of six months may be admitted to the hospital in a state of acute intoxication, recuperate rapidly and leave the hospital in six

or eight weeks. Under usual conditions this man would not relapse for four or five months, therefore the report of the result of hospital treatment should be suspended for a considerable period; at least, a final report on the case should not be made until one or more of the man's episodic attacks of drinking have been successfully combated. On the other hand, if a man who had been a regular or irregular drinker before his hospital treatment, is abstinent for a considerable period after his discharge from the hospital (we have tentatively placed this period at six months), we are justified in considering the man as improved.

2. The conduct and attitude of the patient after his discharge from the hospital. Under this caption we consider the ability of the man to earn his livelihood, and his success in readjusting himself to society.

3. The willingness of the patient to coöperate with hospital authorities after his discharge from the hospital.

Guided by these rules, we have carefully investigated the present condition of all patients discharged and have made careful comparative tests.

The following figures, therefore, have been compiled after continual and prolonged observation of discharged patients; these do not include patients who have not been discharged for a maximum period of six months. During the past five years 1174 patients have been investigated as above described. Out of this 1174, approximately 753, or 64%, are today working and either totally abstinent or drinking so little as not to interfere with their work. Practically all of these men had, before coming to the hospital, dropped below the class of the self-supporting.

The successful treatment of the inebriate in a state institution may, therefore, be said to be dependent, first, on an appreciation of the true nature of the condition; second, on a realization that the inebriate, dependent on the degree and intensity of the condition, demands specialized treatment; third, the necessity for active and continued coöperation with those interests which are genuinely concerned in the problem; fourth, diligent and consistent work and an adherence to the principle established by a definite method of control; and lastly, the education of the public to a proper realization of the status of the institution to the community.

AN ELECTRO-MOTOR BONE OUTFIT AND TECHNIC OF ITS USAGE.

BY FRED H. ALBEE, M.D., F.A.C.S., NEW YORK CITY.

Professor of Orthopedic Surgery, New York Post-Graduate Hospital and University of Vermont.

UNTIL 1911, when the author first began to do his bone grafting operation for Pott's disease,

FIG. 1.—Author's armamentarium for bone work.

1. Calipers. 2. Doyen washers or guards for motor saw. 3. Spray and guard for saw. 4. Twin saw. 5. Dowelling instrument or lathe with cutters of two sizes in place. 6. Right angle twin saw. 7. Wrenches for twin saw and drill chuck. 8. Drill with guard to prevent it penetrating too deeply. 9. Drill chuck and small drill in place. 10. Burr for drilling fractured neck of femur for peg graft. 11. Small circular saw. 12. Large saw. 13. Carver's gonge. 14. Lowman fracture clamp. 15. Berg fracture clamp. 16. Wide osteotome for splitting spinous processes for the insertion of bone graft for Pott's disease. 17. Surgical electric motor. 18. Compasses. 19. Lambotte fracture clamp, large and small.

the bone transplant had been so infrequently used as a surgical agent that no special technic had been developed for its removal. The electric motor circular saw (Doyen) had been used for skull work, driven by either a flexible shaft from a motor on a nearby stand, or by the Hartley-Kenyon apparatus, where the cutting tool is attached directly to the motor shaft,—and, so far as the author is aware, it had not been used in any systematic way for the removal or the modelling of bone transplants.

The author began his spinal work by removing the graft from the tibia with chisel and mallet, and later others made use of the Gigli saw. It was soon found that these methods were not only slow and inaccurate, but that they presented the dangers of bruising, cracking, or fracturing the graft or tibia, or both. This is especially true in adult patients, on account of the brittleness and thickness of the cortex. In the child, on account of the small diameter of the bone, the danger of fracture is evident, although the graft is obtained by means of hand tools with much less difficulty and much less likelihood of fracturing it.

Also, in obtaining grafts 8 in. or more in length, it was found that the hand-tool methods were crude, requiring too much time, tiring the surgeon, and unnecessarily shocking the patient.

In removing the graft with the chisel and mallet, the graft must many times be handled and shaped after its removal, whereas with the circular motor-driven saw a pattern marked in the periosteum with a scalpel can be followed accurately and the graft shaped *in situ* during its removal. The graft pattern is usually obtained by bending a flexible probe or leaden bar into the prepared graft-bed, whose shape is transferred to the tibial surface from which the transplant is to be removed.

In modelling the graft into dowels, wedges, inlays, and in making use of the different well-known mechanical devices, such as tongue and groove joint, dove-tail joints, mortices, etc., the motor outfit is still more indispensable. An accurate cabinet-maker-fit may mean success in many instances where an ordinary crude coaptation would mean failure. Especially is this true in ununited fractures.

The skepticism as to the value of the graft, plus the difficulty in obtaining and moulding it, has undoubtedly delayed the earlier development of the use of this most valuable surgical agent. It is difficult to give an adequate reason why in the rapid advance of surgery the work of osteoplasty has, until very recently, stood for so long a time practically at a standstill, especially in view of the fact that Ollier, in 1858, from ex-

tensive animal experiments and surgical work.—although working in the pre-antiseptic era.—furnished abundant evidence that the autoplasmic bone graft survived and lived when consisting of cortex, periosteum, and endosteum, and implanted into a bony defect where it had function to perform.

As in many other fields of endeavor, electric power has been the chief means of placing this valuable agent at the disposal of the surgeon. In recent years the generalization of the use of electricity for lighting, heating, and power purposes in most hospitals, private dwellings, etc., has also been a potent influence, and has enabled the surgeon always to be in reach of the necessary power for operating his motor outfit—whether he is operating in the city, suburban hospital, or private dwelling. The electric automobile or storage battery can also be made to furnish a movable source of supply, which can be utilized at any time, or place.

FIG. 2.—The manner of holding the motor saw. The connecting wire to the electric wall fixture. The foot switch control. The sterilizable connecting wire to the motor. The sterilized rubber tube connecting the tank of normal saline solution and the spray attachment above the saw. The author's broad thin osteotome for splitting the spinous processes and the calipers for determining the length of the graft are on instrument table.

The ideal surgical electro-motor outfit should measure up to the following requirements:—

1. It should permit of the thorough sterilization of every part which comes in contact with the surgeon or the field of operation, including the electric cable for transmitting the power.

2. It should permit of ready application to all types of osteoplasty, whether situated super-

ficially or in a deep wound; whether the work to be done is the procuring of the graft, the preparation of its bed, the drilling of holes, the removal of bone for the correction of deformity or disease, or to allow the proper approximation and alignment of bone fragments in cases of fracture.

3. It should permit accurate control and guidance of the motor cutting tool in all wounds and at all angles.

4. It should permit easy and convenient control of the electric current.

5. It should be light in weight, small in bulk, and permit of easy transportation.

6. The motor should be universal and adapted to all types of electric current.

7. The motor instruments,—saws of different types, drills, dowel shapers, etc.,—should be held in place in the motor by an automatic catch favoring their speedy interchange.

8. The motor-cutting tools should be constructed similarly to those long-used by the artisan for working hard materials, and should be of sufficient variety to meet every requirement of bone carpentry. The twin saw for inlay work should be so constructed that it can be readily adjusted,—to the fraction of a millimetre,—by the gloved hands of the surgeon at the operating table. The dowel cutters, with drills of corresponding diameters, should vary in size sufficiently to meet all requirements.

9. The motor should furnish enough power to drive rapidly a saw or large drill through the thickest human cortex without tendency to stall.

The author's outfit, described in this chapter, has been carefully devised and perfected with the coöperation of the Kny-Seheer Company, to fulfil all of the above-mentioned requirements. The motor tool is attached directly to the motor shaft; the motor is covered by an adjustable sterilizable shell, enabling the surgeon to hold the motor in his hands while the tool is cutting; the weight of the outfit has been found to be an advantage rather than a detriment in its application, and it is believed that it completely fulfils every demand.

DESCRIPTION OF OUTFIT.

The author's electric operating bone set consists of a small universal motor, *i.e.* one which will operate without readjustment on all types of electric currents, such as direct, alternating, and of varying cycles. If it is to be used on a 220 volt current, a 100 c.p. 220 volt lamp should be placed in series with motor. Electrical engineers have found it impossible to construct a light motor which will resist deterioration from repeated boiling of the motor itself, or any other safe type of sterilization. Both the insulating material and the carbon brushes are liable to disintegration from repeated subjection to heat. Therefore, the Hartley-Kenyon method of removable, sterilizable shells has been adopted, as it seemed by all means the most desirable.

The apparatus consists of a small portable motor with a sterilizable shell which is divided into two parts, so that it can be removed for boiling. A guide handle, which also can be boiled, is adjusted on and at right angles to the small end of the motor over the shell.

A foot switch is supplied to make and break the electric circuit. A long electro-conducting cord is provided to transmit the current from the source of supply. In one end of the cable is a fitting, to be inserted into the electric supply, and on the other end is a connection for the foot switch. Midway between the two terminals, a connecting block is mounted, into which is inserted the connecting cord leading to the operating motor. This connecting cord has fitted onto one end of it a metal tube and connection for the motor, and is the only portion of the electric cable to be boiled.

The foot switch can be used with either side upward. If the corrugated rubber side is upward, the connection is made by pushing down with the foot. If the other side is used upward, the foot should be placed over the entire switch, and by depressing, or allowing the aluminum lever to rise by moving the heel up and down, the current is turned on or off. An important feature of the foot switch is that it contains a speed regulator, so that the more gently the surgeon presses the pedal the slower the tool turns. This is especially a great advantage in starting to drill hard bone. When the pedal is completely depressed the motor is at full speed.

CUTTING INSTRUMENTS

The *single saw*,—about $1\frac{1}{4}$ inches in diameter,—with Doyen graduated washers or guards, is used more than any other of the cutting tools. These saws are of the best steel and are very thin, and are held on the shaft by means of nuts which allow the saw blades to be changed when they become dulled.

The *twin saw* is so constructed that it can be adjusted to any desired width, even to the fraction of a millimetre. It consists of 2 single saws, which can be used singly or together. Each saw is mounted on a separate shaft, one of which is hollow, so that the other shaft can be inserted into it and so bring the saws at any distance apart that may be desired, according to the size of the bone being operated upon and the width of the graft or gutter to be formed.

In determining the size of the inlay or the gutter, the saw teeth are placed on the bone in the manner of a compass or calipers in order to determine the width of the inlay or gutter, and, with the saws undisturbed, the shaft of the proximal saw is prevented from turning by placing the accompanying wrench or a heavy clamp on the flat-sided end of the shaft, while the operator locks the saws together by turning the saw on this shaft away from him by protecting his gloved right hand with a piece of gauze over the saw teeth.

The *dowel instrument* or *lathe* is fastened into the motor by the automatic catch, precisely as are the other cutting tools. Its speed of rotation is reduced about 10 times by steel gears.

The size of the bone graft dowel or nail is regulated by the size of the cutter, which is adjusted in the lathe. The largest cutter is for turning out a bone graft spike for a fracture of the neck of the femur. The smallest one is for making pegs to hold inlay grafts in place. The medium-sized cutter is for making graft nails for pinning the scaphoid to the head of the astragalus in an arthrodesis for advanced flat-foot, or other condition.

The *dowel-shaper* is used by first inserting it into the motor, and then placing the apparatus parallel with and on the edge of the instrument table. While the assistant steadies the motor and lathe by gently pressing the same on the table, the operator, holding with a strong clamp the strip of bone to be shaped, pushes it into the dowel cutter. When withdrawn, it is a perfectly round dowel, and is ready to be driven into the drill hole made by a drill of a size corresponding to the dowel-cutter used. The strip of bone is obtained by means of the single or the twin saw.

The *small saw* is used for cutting the ends of the inlay graft or the strip of bone which is being removed to produce a gutter. On account of its small diameter ($\frac{3}{4}$ in.) the saw does not encroach into the gutter walls while it is cutting across the inlay.

The *guard with spray* is an important attachment. It is connected by a sterile rubber tube with a donegan bag suspended over the operating table, and maintains a constant spray of saline solution on the saw, preventing friction, heat, and flying of the solution.

The *twist drills* are of the type used by the machinist for drilling metal.

STERILIZATION.

The parts to be sterilized are first removed from the motor by releasing the plunger on the end of the electric cable, so as to allow it to come out. This part of the electric cable, from the motor to the black rubber union on the connecting cord, is boiled. The handle and shells are removed and, together with the cutting tools, sterilized by boiling. The part into which the cutting instruments are inserted is removed from the motor, with the long part of the sterilized shell. This is the part which contains the automatic catch. A little sterile vaseline is placed in the motor shaft opening, and the motor is laid aside until the sterilizable parts are ready to be readjusted.

After sterilization, the operator picks up the long part of the shell with his gloved hand and places it on the corresponding end of the motor, which the nurse holds with the small end up. The nurse holds the large end of the motor in the palm of her hand while the surgeon fastens the shell to the other end by turning the shell to

FIG. 3.—Method of putting author's motor outfit together. The sterile shell is turned to the left until it can be turned no further and the arrow on the shell comes in line with the arrow on the motor. The surgeon then has control of the motor and turns it over (see Fig. 4).

ward the right as far as it will go, or until the dart on the shell comes opposite the dart on the motor. The operator can then manage the motor alone by grasping the sterile half shell, which is firmly secured to the motor. The second half of the shell is placed over the other end of the motor and is locked in place to the first half shell by a bayonet fitting. The guide handle is placed over the neck of the motor and securely

FIG. 4.—While the surgeon holds the motor by the sterile shell already attached, he locks the other half shell in place.

fastened by the set screw. The connecting plunger on the side of the electric cable is then inserted through the sleeve on the shell into the motor. This portion of the electric cable, with its metal tube and block connectors, is especially constructed to withstand sterilization by boiling. The corresponding connector is next inserted into the black connecting block in the central portion of the cable leading from the socket of electric supply to the foot switch which the nurse has previously connected and arranged with the foot switch in a convenient position for the surgeon's controlling foot while he is operating. The motor is then ready for use. The saws or the cutting tools are inserted by turning them over a little to the right or the left, while the knurled ring on the end of the shaft is pressed in by the operator's thumb, or until the spring engages the slot on the side of the shaft of the instrument. The cutting tool is unlocked by pressing the knurled ring on the end of the shaft at the same time that the instrument is withdrawn. The action of the motor is controlled by the foot switch which makes and breaks the electric circuit, and the surgeon thus has the uninterrupted use of both hands and the most precise control of the cutting instruments.

FIG. 5.—Illustration of Martel's attachment to author's electrical surgical outfit for laminectomy and skull work. The tool is used to cut away the laminae and the blunt shoe at the end prevents any injury to the dura or cord. The operation is much hastened thereby. A skull flap is produced and turned up in a similar way.

FIG. 6.—Martel's attachment to author's electrical surgical outfit for skull work. The skull is drilled with the large blunt drill, which automatically stops, the instant the inner table of the skull is pierced. The mechanism is so perfect that the dura is never injured. In experimental tests a piece of wet paper placed on the inside of a dry skull has never been damaged by drilling the skull over it. The skull flap is then turned up by inverting the companion cutting tool into the hole thus made (see Fig. 5).

This automatic catch is a great improvement over the screw and screwdriver arrangement for holding the cutting instruments as used on the Hartley-Kenyon motor. In certain plastic work, especially fracture work, it may be necessary at one operation to employ several different cutting tools,—such as two sizes of single saws, twin

saw, different sized drills, and surgical lathe,—and also to interchange these several times. The automatic catch permits of almost as speedy a change of motor tool as of hand instruments, and is a most important feature of the outfit. As far as the author is aware, this is the first automatic catch to be incorporated into an electric motor surgical outfit, and it is almost indispensable to rapid work. Then, again, the screw-driver is a source of danger to the operator's gloved hand, because while loosening or tightening the screw, the motor shaft may turn, allowing the screw driver to push by and puncture the surgeon's glove.

When the motor tool is cutting, the handle,—which is placed at a right angle to the long axis of the motor,—is held in the operator's right hand; the base of the motor is grasped in the left hand, and the right foot manipulates the foot switch, which is placed on the floor beside the operating table, at a place convenient for the operator's foot. If found necessary, the position of the motor and the hands may be reversed.

THE MANAGEMENT OF BREAST FEEDING, WITH CASE REPORTS.*

By C. K. JOHNSON, M.D., BURLINGTON, VT.,

Instructor in Pediatrics, University of Vermont.

It would be presumptuous on my part to attempt to give this group of pediatricians many new points on breast feeding, but this is a subject of much interest to me, and I thought that this short paper, even if much was a restatement of old observations, might stimulate in yourselves and more especially through you the general practitioner and the laity a more keen appreciation of the value of breast feeding. Almost daily I see infants put on the bottle, when with a little tact and patience I believe many of them could have with much benefit remained at the breast fully or partly for some weeks longer.

One would judge from the numerous articles written on artificial feeding and the scarcity of them on breast feeding that everyone was supposed to know all about the natural method. In fact, do we not over-estimate our ability to adapt artificial food to infants? During my post-graduate work it has always seemed to me that breast feeding did not receive its deserved amount of time. Much depends upon the general practitioner and his attitude, as with him rests the responsibility of ascertaining sometime previous to the expected date of delivery that the breasts and nipples are in good condition, any sunken nipples receiving appropriate treatment at this time. He should also inquire as to the mother's habits, digestion, condition of the

bowels, etc., as these all have an important bearing on successful nursing, and the prospective mother should be impressed with their importance.

I recently saw an infant, the first child, put on the bottle because of sunken nipples, which could undoubtedly have been prepared for their natural function had the necessary precautions been taken earlier.

One frequently sees a mother try to nurse her infant for two or three weeks. Then the breast milk becomes deficient. This occurs because the mother is tired out by her new duties, from lack of sleep and by seeing her infant losing in weight. The mental attitude has an unfavorable influence on the milk secretion, and after a little time, of her own initiative or by the advice of a physician, the infant is put on a bottle.

Dr. Griffith has well said that the adjustment of equilibrium between the mother's milk and the infant's digestion should be awaited and no haste made to give up the natural food until we are well satisfied that a change should be made.

Lucy Nash says that few mothers understand that the baby's cry during the first two or three days before the flow of milk becomes established, is not a cry of hunger, but a natural process for the full expansion of the lungs. In consequence they become nervous and get into a nervous state which affects the milk supply unfavorably.

Very recently a mother told me that she wanted to nurse her infant, then six days old. She was giving the bottle four or five times a day until the breasts became active. The breast milk was slow in coming as might be expected. I advised that all artificial food be stopped and that the infant be put to the breast at regular intervals. A report three days later said that the breast supply was sufficient and the infant contented.

The breast milk is often said not to agree with the infant. Very frequently, however, the milk is not analyzed, and even if this is done it may be misleading owing to the method of obtaining the sample to be analyzed. I recall one case where the laboratory report said that the milk was very poor and insufficient to nourish any infant. The infant, however, remained at the breast and continued to thrive. I find that the majority of general practitioners do not appreciate the marked variation in fat percentages between the first and last milk obtained from the breast. My cases reported in this paper well show this variation. In one instance in a multipara I emptied one breast with a breast pump, saving the milk in four consecutive samples, the analysis of which follows:—

	Fat.	Proteid.	Sugar.	Ash.	Total Solids.	Water.
No. 1	2.23	.98	6.60	.17	9.98	90.02
No. 2	4.32	1.07	7.16	.19	12.74	87.26
No. 3	6.84	1.03	5.50	.16	13.53	86.47
No. 4	7.92	1.12	—	—	—	—

It is needless for me to mention the relation of infant mortality to breast feeding. It might,

* Read before the New England Pediatric Society, March 26, 1915.

however, be wise for us as physicians to impress this point more fully upon the mother. I believe that most mothers who thoroughly understand the value of even two or three months of breast feeding to their infants would make every possible effort to perform this duty.

Frequently an infant is allowed to nurse too often and at irregular intervals, both of which are bad for mother and infant.

Dr. Fisher says that 90% of poor mothers are able to nurse their infants, while only 17% of rich mothers are able to do so. This may be correct but from my experience I think that he gives too great a difference between the two classes, the 17% being too low.

Much has been written regarding the nursing mother's diet, and I believe that many physicians are inclined to restrict so much as to be a hardship for the mother. She gets to feel that this or that article of food is disturbing her infant and she becomes nervous in consequence.

I am inclined to allow a liberal diet, limiting only things known to disagree. I fully believe that the condition of the mother's nervous system is more important than her diet if that is reasonably good.

It has been said that a mother has an abundance of good milk and could nurse her infant, or that she has a scanty supply of poor milk and could not perform that duty.

Dr. McClanahan asks, Is there no middle ground between breast feeding and bottle feeding? He strongly advocates supplemental feeding in suitable cases.

I have even been criticized by physicians for trying to use supplemental feedings. I am, however, having good success with this method in many cases and feel that others would be well paid for their efforts along this line. I have to-day at the time of this writing seen a five-month infant, weighing 16 pounds and in excellent condition. The mother during the early weeks of nursing had very little breast milk, and her physician, a leading pediatricist, advised that the infant be put on the bottle. The mother, however, persisted with the breast feeding, the infant doing well. At three months one nursing was replaced with cow's milk. This is continued at present, the remaining feedings being from the breast.

This illustrates that it is not always possible to predict the functional activity of the breast.

The following cases are cited as representative of many in my files.

CASE 1. Male; one month of age; birth weight $\frac{1}{2}$ pounds; weight when seen at one month, 9 $\frac{1}{2}$ pounds; breast-fed; nursing at two-hour intervals. There had been slight vomiting from birth, but the main difficulty was persistent colic, with loose stools, 3 to 5 daily, containing many fat curds. The infant had considerable eczema about the face and shoulders. The mother had become discouraged and tired out from lack of sleep so that it had been decided to put the baby on the bottle. An analysis of the breast milk showed the fat in the sample taken before

nursing to be 2.25%, that taken after nursing 7.96%. The mother was directed to nurse her infant every three hours, for five minutes, this to be preceded by one-half to one ounce of water. Within a short time all vomiting and colic had stopped and the eczema much improved.

CASE 2. Male, five weeks of age. This infant had been breast-fed for four weeks, during the latter part of which the mother, in consequence of her extra duties, became tired and nervous. The infant became fretful and colicky; the weight stationary at 8 $\frac{3}{4}$ pounds. The milk became scanty and at four weeks breast feeding was discontinued. The artificial food did not agree and I was consulted when the infant was five weeks of age. I returned the infant to the breast, supplementing a small bottle feeding after each nursing of five minutes' duration. The mother was as far as possible relieved of care and worry. The breast secretion soon improved and an analysis showed the first sample, fat 5.76%, the second, 7.75%. The artificial food was discontinued and three-hour nursings of five to eight minutes' duration ordered, preceded by water. The vomiting and colic were soon relieved and the infant began gaining six to eight ounces a week. At twelve weeks the weight was twelve pounds.

CASE 3. Male; the second child; birth weight 9 pounds; breast-fed. From the first this infant had severe colic, keeping the household upset day and night. The mother was nursing the infant every two hours, day and night, in an attempt to keep it quiet. The breast was emptied at each nursing yet the baby seemed hungry. The mother was tired and nervous. The infant vomited frequently, the stools were numerous and contained many fatty masses. The weight had gradually increased to 10 pounds.

I first saw this infant when it was one month of age, at which time it had been decided to discontinue breast feeding. An analysis of the breast milk showed fat, 3.6%, and 6.2%. Five to eight-minute nursings at three-hour intervals were ordered after each of which the infant was offered one ounce of dextrinized barley gruel in a bottle. It was arranged so that the mother could have good rest at night and as a result conditions improved at once. A small amount of skim milk, and still later whole milk, was given with the gruel. The artificial food has been gradually increased as the breast secretion demanded and at five months the last breast feeding was given. At this time the baby weighed sixteen pounds, was firm and could nearly sit alone.

CASE 4. This infant, the first child, was first seen during my dispensary service, November 25, 1914. At this time it was two months of age, its weight was 12 pounds. It had been breast-fed from birth and the mother brought the infant for advice as to what food to give, as the breast milk was deficient. The breast was emptied at each nursing and the infant not contented. I was unable at this time to secure milk for analysis. The mother was advised to nurse her infant every three hours for five minutes; following which two ounces of modified milk were offered, care being taken to have a nipple with small holes. The amount of artificial food was increased as seemed necessary. This infant was brought to the dispensary quite regularly for a period of nine weeks, then the mother went out of the city on a visit. This infant was next

seen at six months of age, at which time the weight was 17 pounds and the general condition good. The modified milk had not been increased. The breast milk of fairly good quantity showed the following analysis, before nursing, fat, 2.72%, proteid .79%; after nursing, fat, 11.52%, proteid not obtainable as sample was small.

THE PRESENCE OF *B. DYSENTERIAE*, *B. PROTEUS VULGARIS*, *BACT. WELCHII*, AND *MORGAN'S BACILLUS* No. 1, IN THE STOOLS OF CASES OF INFECTIOUS DIARRHEA.

BY CARL TEN BROECK, M.D., BOSTON,

AND

FRANK GARM NORBURY, BOSTON.

[From the Laboratories of the Boston Floating Hospital and the Department of Comparative Pathology, Harvard University Medical School.]

THE interpretation of the results of any bacteriological study of a disturbance of the gastrointestinal tract is extremely difficult, owing to the great number and variety of organisms present, and to the fact that under abnormal conditions, some of these may multiply so rapidly as to lead the investigator to believe that they are the cause of the condition rather than the result of it. We all work under more or less of a bias, and if we decide that some one organism is the cause of a pathological condition we are apt to spend most of our time in searching for this one bacterium and in neglecting other factors which may be the true cause of the trouble. We believe that this accounts to a great extent for the importance attached to the several organisms that have been described as the cause of infectious diarrhea in infants. In taking up a study of this condition we decided to examine a large number of stools for four of the organisms that have the best evidence in their favor as being the etiological agent, rather than to attempt a complete bacteriological examination of the stools. These organisms are *B. dysenteriae*, *B. proteus vulgaris*, *Bact. welchii*, and *Morgan's bacillus* No. 1.

The study was made on the Boston Floating Hospital during the summer of 1914, and while we regret that the work has not extended over more than one summer, we feel that our observations should be recorded. The hospital provides an ample supply of material, and a well equipped laboratory. A spirit of coöperation on the part of the staff prevails that goes far towards making the work a success.

Infectious diarrhea is characterized by more or less fever and prostration, tenesmus, and the passage of an increased number of stools. These

stools contain mucus, and frequently blood and pus. A Gram-stained preparation made from the feces shows pus cells and bacteria, the majority of which are short Gram-negative rods lying free or in leucocytes and surrounded by a clear zone resembling a capsule. In addition, the stools have a characteristic odor that is recognized by those who have had considerable experience in examining them. The disease is an important one, in Boston at least, as it is very prevalent in the summer months, and the mortality among the hospital cases rises to between 40 and 50%.

The association of organisms of the dysentery group with these cases was first noted by Duval and Bassett¹ in 1902. They found dysentery bacilli in the stools of forty-two out of fifty-three cases examined. In 1904 was published "The Bacteriological and Clinical Studies of the Diarrheal Diseases of Infancy from the Rockefeller Institute of Medical Research." The laboratory studies were made by several workers under the direction of Dr. Flexner, in a number of eastern cities of the United States, and while the results of the different observers vary considerably, the dysentery bacillus was found in 63.2% of 412 cases examined. The work of Weaver and Tunnickliff,² Wollstein,³ Kendall⁴ in this country, and of Leiner,⁵ Auché and Compana,⁶ Gildemeister and Baerthlein,⁷ Siegel,⁸ Bauer, Ellenbeck and Fromme,⁹ Weihe and Sehäuser¹⁰ Baerthlein and Howard,¹¹ and others in Europe, shows that the dysentery bacillus is found widely distributed in association with these cases. Immune substances such as agglutinins and complement fixing-bodies for the dysentery bacillus, have been found in the blood of these cases by a number of observers.

Tissier,¹² Klein,¹³ and Kendall¹⁴ have shown in certain cases which are clinically infectious diarrhea, that spores of organisms belonging to the groups of *Bact. welchii* are present in apparently increased numbers. The last observer found that a certain percentage of cases from which he was unable to isolate dysentery bacilli, passed stools, a small portion of which inoculated into milk and the milk heated for twenty minutes at 80° and then incubated, caused a "stormy fermentation" in this medium. It is stated that stools showing dysentery bacilli and those from normal cases did not give this reaction. These cases are said to improve on a diet of buttermilk and to do badly on a high carbohydrate diet, while the cases of infection with the dysentery bacillus are said to react in the opposite manner. He concludes that organisms of the *Bact. welchii* group are the etiologic factor in cases giving this reaction, and says that the number of these cases varies from year to year. So far as we have been able to learn, no immune bodies have been demonstrated in the blood of these patients and very few cultural studies on the organisms isolated have been published.

In 1897, Booker,¹⁵ working in Baltimore, studied a series of these cases and decided that *B. proteus vulgaris* was the cause of the disturbance, and for the last few years Metchnikoff¹⁶ and his pupils have been working on this organism as the cause of summer diarrheas in infants. They give only a very brief description of their cases and state that blood and pus were present in the stools in only a few instances, so it is evident that many of their cases cannot be classified as infectious diarrhea as it is understood in this country. They seldom find *B. proteus vulgaris* on plates of Conradi-Drigalski medium made directly from the feces, but isolate it by making a stab culture from the stool into gelatine, and within from twenty-four to forty-eight hours transferring a loop of the liquefied gelatine to the condensation water of an agar slant. The greater motility of *B. proteus vulgaris* enables it to climb onto the surface of the slant more rapidly than the other organisms, and if it is present, it is often isolated in pure culture at the end of twenty-four hours. Metchnikoff's work has extended over a period of five years, and during this time he has examined two hundred and eighteen stools from cases of summer diarrhea and has isolated *B. proteus vulgaris* in two hundred and four cases. He only mentions having examined six normal stools and found this organism present in two of these. In thirty-three stools that were slightly abnormal, he found it present in eighteen. Rabbits only a few days old and young chimpanzees, when fed the stools from diarrheal cases, developed a severe diarrhea, and cultures from their intestines showed *B. proteus vulgaris* to be present in great numbers. Metchnikoff does not mention having isolated the dysentery bacillus from any of his cases, but Bertrand,¹⁷ who studied fifty-five diarrheal stools and found *B. proteus vulgaris* in all, isolated the dysentery bacillus in fifteen cases. From the stools of twenty-four cases whose digestive tracts were apparently normal, the latter observer isolated *B. proteus vulgaris* only twice and the dysentery bacillus four times.

Morgan¹⁸ has studied a very interesting organism which he regards as a factor and perhaps the most important one in the infectious diarrheas found in England. From one hundred and twelve cases that were studied, this organism, known as *Morgan's bacillus No. 1*, was isolated on MacConkey's bile salt neutral red agar plates in forty cases, while dysentery-like organisms were found only five times. Agglutinins for the Morgan bacillus were not found in the blood of cases from which it was isolated. When cultures of this organism were fed to young rats, a severe diarrhea, followed by death, resulted.

With this brief review of some of the more important papers bearing on the organisms under consideration, we will give the results ob-

tained in our search for them in the series of cases studied.

The stools were passed into clean but not sterile pads, and as soon as possible were sent to the laboratory, where the various media were inoculated at once.

B. dysenteriae. For the isolation of the dysentery bacillus a suspension of the stool was made in bouillon and streaked over the surface of previously prepared Endo plates containing two per cent. of agar. After from sixteen to twenty hours' incubation, the plates were examined and suspicious colonies transferred to bouillon, and after five hours' incubation, transfers from the latter were made to two tubes of Hiss semi-solid media, one containing lactose, and the other mannit. Lactose was used, since occasionally cultures from colonies resembling dysentery on the Endo plates were found to produce acid in lactose, these being a rule cocci. After these tubes had been incubated over night, the bouillon cultures whose sub-cultures showed growth characteristic of dysentery, were used for agglutination. The macroscopic test was used and was made by mixing one cubic centimeter of the culture with one cubic centimeter of a 1-500 dilution of anti-dysentery "Flexner" (mannit-fermenting strains) horse serum obtained from the Rockefeller Institute for Medical Research. This serum in a dilution of 1-1000 caused a complete agglutination of the mannit-fermenting dysentery bacilli after the tubes had been incubated for two hours and then allowed to stand in the cold for twenty hours.

The colonies of the dysentery bacillus on Endo plates are circular, translucent, and resemble drops of paraffine from one to two millimeters in diameter. While these organisms apparently grow readily on this medium, the number of colonies found in any one case was never very great, and oftentimes we failed to get them after repeated trials, though we were practically convinced from the appearance of the case that they were present in the feces. Repeatedly, the diagnosis was made on sub-cultures from the only dysentery-like colony on the plate. In two instances we were unable to isolate dysentery bacilli from the feces, in four separate attempts, yet they were obtained with ease at autopsy from the mucosa of the large intestine. In another case that clinically was infectious diarrhea and where the blood culture showed dysentery bacilli, we were unable to isolate these organisms from the feces though seven attempts were made.

Duval and Bassett¹⁹ state that for the isolation of the dysentery bacillus, the media should be *distinctly acid to litmus* and they further say, "Should the reaction be neutral to litmus, the difficulty of isolation of *B. dysenteriae* is very much increased; and in the presence of an alkaline reaction, isolation is rendered almost impossible." Should this be true, it is not surprising that in this day of selective media (that are always alkaline to litmus) the dysentery bacillus

is so seldom found. This, together with the apparent scarcity of the organisms in the feces and the fact that a negative report is often given after one examination, may account for their being missed in a certain number of cases. It has been our experience that while this bacillus is very difficult to isolate from the stools, with the method we used, we could readily isolate it from the mucosa of the large intestine after death. We made a few attempts to isolate it directly from the mucosa of the rectum during life by the help of the proctoscope, but were not successful. A careful comparative study of the methods of isolation of the dysentery bacillus and an attempt to get some good "enrichment medium" is greatly needed, and we regret that the pressure of other work prevented our taking up this problem.

During the summer, ninety-one cases were diagnosed clinically as infectious diarrhea, but in twelve of these we did not have an opportunity to make a careful bacteriological examination of the stool. Of the remaining seventy-nine cases, fifty-four, or sixty-eight per cent, showed dysentery bacilli. Many of the cases that were negative entered the hospital after they had been sick some days, and in some instances two weeks after the onset of the disease. We feel certain that many of them had dysentery bacilli in their stools, though we were unable to isolate them. The blood of these cases should have been tested for agglutinins, but lack of time prevented our making these tests.

Not a single culture of the Shiga bacillus was isolated. All the infections were due to organisms of the mannit-fermenting group of dysentery bacilli and the majority of the cultures, sixty-eight per cent., belonged to the Hiss Y type. That is, they formed acid in media containing dextrose and mannit, but not in lactose, saccharose, maltose, and dextrin. The remaining cultures were about equally divided between the Strong and the Flexner types. This differentiation of the mannit-fermenting dysentery bacilli into groups is very unsatisfactory, as the cultures vary so in their ability to attack the higher carbohydrates. Intermediate forms between each two of the groups are common and it is difficult to classify them correctly. The organisms that ferment saccharose and maltose tend to lose this property and then would come under the Hiss Y group. This has occurred with several of our cultures and also with the "Flexner-Harris" culture that has been in our laboratory for a number of years.

The stools of twenty-eight cases, with a diagnosis of diarrhea due to indigestion, were all negative for dysentery bacilli. In marked contrast to the cases of infectious diarrhea, the Gram-stained preparations from these stools showed few or no leucocytes and a predominance of organisms that were positive to Gram.

The evidence in favor of the dysentery bacillus as the cause of infectious diarrhea in infants

is its association with the majority of cases, the abundance of these organisms in the mucosa of the large intestine in acute cases, and the development of immune bodies to this organism in the blood of patients with this disease. While it has occasionally been found in the stools of individuals with an apparently normal digestive tract, these persons usually give a history of a previous diarrhea or an association with a case of this disease. The fact that it is apparently absent in a certain percentage of typical cases may be accounted for in some of the cases by the difficulty of isolation of the organisms, the use of unfavorable media, or to the examination being made rather late in the course of the disease.

Bacterium Welchii. The medium used in determining the presence of this organism was sterile fat-free milk in test tubes, the depth of the fluid being approximately six centimeters. A loop of the feces was transferred to the milk and emulsified by rubbing against the sides of the tube, after which the tube was immersed in a water bath at 80° C. for twenty minutes, and then incubated at 37° C. for twenty hours. At the end of this time the milk in some tubes was unchanged, in which case the reaction was said to be negative; in others, there was a solid coagulum, a smear from which showed organisms having the morphology of *Bact. welchii* when the reaction was said to be questionable, or there was the so-called "stormy fermentation," which was said to be a positive reaction. We fully realize that this is at best only a qualitative test for spores of gas-producing organisms, and while the organisms may have the morphology of *Bact. welchii* they should be isolated and studied, but we had neither the time nor the facilities for doing this work.

Simonds²⁰ has studied a number of strains of *Bact. welchii* and subdivides them into four groups, according to their action on glycerin and inulin. In the few cultures from infants' feces that were studied, those from diarrheal stools do not differ from those of the normal infants.

The results of the tests made on the stools from cases of infectious diarrhea and on those from various other cases are given in Table I.

TABLE I.

TESTS FOR SPORES OF ORGANISMS GIVING THE REACTION IN MILK THAT IS CHARACTERISTIC OF *BACT. WELCHII*.

Clinical Diagnosis.	Number of Cases.	REACTION.					
		Negative.		Doubtful.		Positive.	
		No.	%	No.	%	No.	%
tufect. diarrhea. (Dysentery bacilli found.)	53	35	66	12	23	6	11
Infect. diarrhea. (Dysentery bacilli not found.)	37	19	51	11	30	7	18
Indigestion with diarrhea	34	16	47	9	26.4	9	26.4
Malnutrition	14	5	36	5	36	4	29
Normal	13	2	15	6	46	5	38

It will be seen that while this reaction in milk is produced by a certain number (11%) of cases showing dysentery bacilli, it is given by a greater number of cases of indigestion (26.4%), and by a still greater number (29%) of cases of malnutrition. In normal stools it was found with the greatest frequency, and while the number here recorded is small, the observations are confirmed by others made some years ago by one of us working under the direction of Dr. Theobald Smith and by the work of Knox and Ford,²¹ who found *Bact. welchii* in the stools of eighteen children with normal digestive tracts. This organism is an inhabitant of the digestive tract of normal man and many animals, is frequently found in milk, and has been found by us to be present in the "Eiweiss" milk that has been recommended as a treatment for these cases. It is difficult to understand how an organism having such a wide distribution and being an inhabitant of the normal digestive tract can be the cause of this condition, and we agree with Knox and Ford that sufficient evidence that *Bact. welchii* is the cause of infectious diarrhea in children has not been produced.

In order to say that *Bact. welchii* is a possible cause of infectious diarrhea one should be able to show repeated negative examinations for the dysentery bacillus in the stools and negative immune-reactions for this bacillus in the serum. In addition, demonstration should be made by plate cultures that the spores or the vegetative forms of *Bact. welchii* were present in greatly increased numbers, and immune-bodies to this organism should be found in the blood. It might also be that cultural differences could be found between the organisms from cases of infectious diarrhea and those from normal individuals.

The obtaining of a "stormy fermentation" in milk inoculated with feces and then heated does not indicate that *Bact. welchii* is present in increased numbers, for we have shown that eight spores will produce this change in milk and a milligram of feces from a normal infant often shows many times this number of spores of this organism.

Early in the disease of infectious diarrhea the reaction for *Bact. welchii* is usually absent, but it appears after the acute stage has passed. This may account for the statement that cases showing this reaction usually recover, or it may be that this organism has an action antagonistic to the dysentery bacillus.

B. Proteus Vulgaris. For the isolation of this organism, stab cultures were made into gelatine from the suspension of the stool in bouillon, and after several days' incubation, provided the gelatine was liquefied, attempts were made to isolate it by transferring a loop of the fluid medium to the condensation water of slanted semi-solid media. Thirty-one cases showing dysentery bacilli were examined in this way and in twenty-one of these there was no liquefaction of the

gelatine, so we have no evidence that proteus was present. In the ten cases where the gelatine was liquefied the organisms isolated in three cases belonged to the group of *B. coli*; in three to the *B. cloacae* group; and in four to the *B. proteus vulgaris* group. We, therefore, conclude that *B. proteus vulgaris* is frequently absent in cases of infectious diarrhea, and we have no evidence that it plays any part in the process. Its association with the more simple diarrheas is a subject that we will not attempt to discuss.

Morgan's Bacillus No. 1. This organism was isolated from Endo plates three times where dysentery bacilli were also present and six times where we were unable to isolate the latter organism. It is an extremely interesting organism from a bacteriological point of view as it attacks the hexoses forming acid and gas, but has no action on the di- or poly-saccharides or on the alcohol mannitol. While it may play some part in the disease, we have no evidence that it is the primary cause of the trouble.

The same may be said of the organisms of the para-typhoid group and of pyocyanus and the streptococci that are encountered so frequently. They must modify the disease of infectious diarrhea in one way or another, but we regard them as secondary invaders that multiply on account of the abnormal conditions produced by the dysentery bacillus. The part they play in the disease can be determined only by the most careful quantitative examinations of the stools and of the contents of the digestive tract at various levels, immediately after death, correlated with careful clinical observations. The study of the spontaneous diarrheas that occur in the lower animals, especially the disease that so frequently affects monkeys, should also throw light on this disease of children.

CONCLUSIONS.

1. In order to isolate the dysentery bacillus from the stools of cases of infectious diarrhea, repeated attempts often have to be made, and the number obtained may be very few.

2. Dysentery bacilli, of the mannitol-fermenting type, were isolated from sixty-eight per cent. of the seventy-nine cases studied.

3. Organisms of the *Bact. welchii* type are occasionally associated with dysentery bacilli, but they are found more frequently in the cases of simple diarrhea and still more frequently in normal stools.

4. We have no evidence that *Bact. welchii*, *B. proteus vulgaris*, *Morgan's bacillus No. 1*, the para-typhoid bacilli, or *B. pyocyanus* are the cause of infectious diarrhea, though they probably influence the course of the disease that is apparently started by the dysentery bacillus.

A NOTE ON THE INVASION OF THE BODIES OF INFANTS BY *B. DYSENTERIAE*.

BY CARL TENBROECK, M.D., BOSTON.

[From the Laboratory of the Boston Floating Hospital and the Department of Comparative Pathology, Harvard University Medical School.]

THE isolation of dysentery bacilli from the blood culture made from an infant suffering from an acute attack of infectious diarrhea, made it seem worth while to study a series of cases, in order to determine the frequency of the invasion of the body by this organism. In the text-books one finds the statement that this is a rare occurrence, but in the literature there are a number of cases reported of positive cultures from the blood or from the organs.

Rosenthal,¹ in fifteen autopsies on adults, found dysentery bacilli in the liver and heart's

blood in one case. Aveline, Boycott, and McDonald² report one case, in an adult, where dysentery bacilli of the mannit fermenting group were isolated from the spleen. Mühlmann³ found dysentery bacilli in the liver three times and in the spleen once. Brückner⁴ found organisms of the mannit fermenting type in the liver of an adult. Darling and Bates⁵ isolated the Shiga bacillus from the peripheral blood of an adult on the seventh day of the disease.

The reports of the invasion of the body of infants by the dysentery bacillus are more numerous than those on adults. Duval and Bassett⁶ found them in the liver in one case. Howland⁷ made cultures from the organs of eight cases and did not succeed in finding the dysentery bacillus in a single instance. Knox and Schorer⁸ found them in the liver in two cases. Kendall⁹ isolated the Shiga bacillus from the blood of an infant on the sixth day of the dis-

ease. Gildemeister and Baerthlein¹⁰ found dysentery bacilli of the mannit fermenting group in one case, and Baerthlein and Howard¹¹ found the same type of organisms in the liver or spleen of five cases.

Most of the writers do not state the number of cases examined, only reporting the positive results, and in many instances the type of organisms found is not given. There are only two instances of positive blood cultures, and in both of these the infection was due to the Shiga bacillus.

Early in the season of 1914 on the Boston Floating Hospital, a male baby with a provisional diagnosis of typhoid fever, entered on the service of Dr. Young. There was marked prostration, a temperature of 105°, and the stools were not those of infectious diarrhea. The onset of the trouble began two days before entrance. On the third day of the disease a blood

culture was made, and much to our surprise *B. dysenteriae* was isolated. In order to be sure of our findings, cultures were made a second time from the blood diluted with bouillon and a second strain of dysentery bacilli was isolated. Both of these cultures were agglutinated by anti-dysentery serum and in their sugar reactions corresponded to the Flexner type. That is, they form acid from dextrose, mannit, maltose, saccharose, and dextrin.

The patient soon passed stools that were characteristic of infectious diarrhea and after a long illness eventually recovered. Seven attempts were made to isolate dysentery bacilli from the dejecta, but they were never successful.

Blood cultures were made from eleven other cases of diarrhea, six of which had dysentery bacilli in the stools, the other five being clinically infectious diarrhea, but the organisms were not found in the dejecta. The cultures were all made a number of days after the onset and were all negative for dysentery bacilli and all but two were negative for all organisms. These two showed a coccus that may have been a contamination from the air.

In addition to the blood cultures, fourteen cases were autopsied soon after death, and a bacteriological study was made of the various organs. In making cultures the surface of the organ was seared and a piece of tissue the size of a bean was transferred to bouillon. As soon as the cultures showed growth, pure cultures were obtained and the organism was studied. Before an organ was said to be sterile, transfers were always made to a tube of sterile bouillon, even though there was no clouding of the original culture. The organisms classed as belonging to the *B. coli* group were motile and formed acid and gas in lactose, but their action on the other carbohydrates was not studied.

It will be seen by the results given in the table that while the liver and spleen of these cases often contained organisms, the dysentery bacillus was never found there.

Some few attempts were made to study the distribution of dysentery bacilli in the digestive tract. They were never found in the mucosa of the stomach, duodenum, or jejunum, but were abundant in the wall of the lower portion of the ileum and throughout the large intestine. The failure to find them in the three cases tabulated was probably due to the fact that plate cultures were not made from the suspension of the mucosa, but we depended upon streak cultures made on agar slants. The dysentery bacilli from all of our cases belonged to the mannit fermenting group.

SUMMARY.

B. dysenteriae of the mannit fermenting group has been demonstrated in the circulating blood of an infant suffering from infectious diarrhea. Eleven blood cultures made from other cases of diarrhea and cultures made from the organs of fourteen cases were all negative for

dysentery bacilli, and the one positive finding is probably an accidental invasion rather than a usual feature of the disease.

Reports of Societies.

NEW ENGLAND PEDIATRIC SOCIETY.

MEETING OF MARCH 26, 1915, HELD AT THE BOSTON MEDICAL LIBRARY.

The President, Dr. E. M. BUCKINGHAM of Boston was in the chair.

The following papers were read:—

1. The Management of Breast Feeding, with case reports.* C. K. Johnson, M.D., Burlington, Vermont.
2. Air, Water and Light as Curative Agents. Roland G. Freeman, M.D., New York City.

DISCUSSION.

DR. MAYNARD LADD: I have been asked to open this discussion, and there are one or two points that I would like to emphasize in Dr. Johnson's paper which are important. First, as to the weighing of the baby before and after nursing. I think that this is not done as often as it should be. By so doing we can secure a very accurate idea of the amount of milk which the child is getting, particularly in the early days, so that if the amount is insufficient we may give supplementary feedings until the breast milk comes in sufficient quantity to supply the needs of the child. If the supply is insufficient, the effect of the supplementary feedings on the mother is beneficial, for she is saved the anxiety which comes from seeing her child insufficiently nourished. This habit of weighing the child from time to time in the early days has given results now and then that have been rather surprising, especially with reference to the quantity of food that the new-born infant may occasionally take. I have frequently seen vigorous infants, nursing from the mothers with an abundant supply of milk, take from $3\frac{1}{2}$ to 4 and even 5 oz. at a feeding,—a much larger quantity, of course, than is desirable. I think that the cases in which the supply of milk is large and the child vigorous and taking a large quantity, are the ones likely to do best on the long intervals between feedings. These babies often do perfectly well on $3\frac{1}{2}$ and 4-hour in-

* See JOURNAL, page 278.

tervals, whereas the baby who is getting only 1 or 2 ounces at each nursing is not likely to go through that long interval without making his wants known.

Another point,—in regard to the analysis of the breast-milk. The analyses we get are often misleading. When we wish to get an idea of the quality of the mother's milk, especially in a case of disturbed digestion, we try to milk out with our fingers, or by means of a breast-pump a sufficient amount of milk for examination. Sometimes we exhaust the quantity in the breast by the withdrawal of 1 or 1½ ounces, and yet if we have previously weighed the baby before and after nursings, we find that it has taken from 3 to 4 ounces. There is no reason to believe that the large quantity of milk which the child gets will have the same chemical composition as the small amount which we have been able to withdraw artificially for examination. That is a point which should be borne in mind where we have to empty the breasts of nervous mothers. When their supply is small it is very difficult to get enough milk to make a fair sample of that which the babies are getting.

In regard to the diet of the nursing mother, the suggestion of Dr. Southworth of the beneficial results of corn meal gruel is certainly worth mentioning. It seems to me that it has some virtue over other cereals, and is worth trying, particularly in cases where the quantity of milk is lacking.

Mothers are sometimes very unfairly blamed for not nursing their babies. They should of course be encouraged to nurse to the extent of their ability, but there is no question that many must fail, in spite of our best efforts to preserve the quality and quantity of the breast-milk. The popular idea that every woman, who is milking, can nurse her child often leads to unjust criticism of the mother who has to put her baby upon substitute feeding because of the unavoidable failure of the natural supply.

Dr. Jouxson (in closing): I fully agree with what Dr. Ladd has said in regard to weighing, only I should add to that, that it is important to have more than one weighing in the 24 hours. The infant should be weighed after every nursing in the 4-hour period, for the amounts taken at the different nursings vary very greatly in quantity, from ½ oz. at one feeding to 4 or more at the next, and so on.

Abstract of paper on

AIR, WATER AND LIGHT AS CURATIVE AGENTS.

By DR. ROWLAND GODFREY FREEMAN, New York: This paper emphasized the potency of air, water and light as curative agents and their great advantage in most cases over medicinal treatment.

It took up the sedative and stimulating effects of baths at different temperatures. Some of the results obtained by heliotherapy in France and Switzerland were reviewed and a plea made for a larger use of this treatment, particularly in tuberculous cases. Treatment of disease in well-ventilated rooms or preferably out of doors was then considered, with some consideration of the action of fresh air on the child; the method of carrying out such open air treatment, and finally the results of such treatment in tuberculosis, measles, pneumonia and abnormal conditions of the blood.

Dr. J. P. MORSE: I am very glad indeed to hear this paper of Dr. Freeman, and to hear him emphasize the advantages of real old-fashioned medicine. It seems to me that he ought to add good food to

air, water and light in the treatment of disease. I am very glad, also, to hear what he says about artificial ventilation, which in my opinion does not ventilate at all. It may surprise some of you, moreover, to learn that it is against the laws of Massachusetts to build a schoolhouse or a public hall without installing a special system of artificial ventilation. You have got to have it, whether you use it or not.

I must say that my experience makes me believe that, while fresh air is a good thing in bronchitis and croup, cold air is not a good thing in the said affections, and that cold air does make them worse. I have used the fresh-air treatment in pneumonia ever since Dr. Northrup brought it to our attention a number of years ago; in fact, I may say that I fought shoulder to shoulder with Dr. Northrup in the beginning, but I am not convinced, nevertheless, that the mortality in pneumonia in children has been diminished by the fresh-air treatment. It seems to me that it is very hard in comparing statistics to bring in bronchopneumonia for comparison, because it makes so much difference what is called bronchopneumonia. You may have a bronchopneumonia which is merely nothing more than a mild bronchitis, or you may have the very severe types of bronchopneumonia. As regards mortality, they are two different diseases.

Dr. E. M. BUCKINGHAM: With regard to the general effect of fresh air, I happened to have charge of the contagious wards of the City Hospital the winter before the opening of the present service; and the diphtheria ward was badly crowded, because of an extensive epidemic. About the first of February, I had moved to a piazza on every sunny day, as many patients as it would hold, an appreciable proportion of the whole, the patients spending the whole day in the open. I cannot now give statistics, but the effect on the general appearance of the service was marked and immediate, on some individual patients particularly so.

As to the effect of cold air on bronchitis, I would say that one of my duties many years ago was to arrange for out-patient clinics. One cold winter, I often found striking cases of sonorous râles and reserved them. It was very common, however, when the students arrived, and the child had been waiting for an hour, more or less, in a warm room, to find that these râles had disappeared completely. This happened so very often that there could be no accident about it.

Dr. J. B. HAWES: Dr. Freeman, in his valuable paper, has brought up so many interesting points that it is impossible to dwell upon them all. I was very glad to hear what he had to say upon the comparative uselessness of artificial systems of ventilation. I have felt very strongly for a long time that so-called "baked air," no matter how perfect the system which may conduct it into rooms, has lost a certain most important and vital quality.

I would also emphasize the importance of cold sponge baths in the morning, but would sound a note of warning in this regard. Among school children particularly, this is apt to be carried to an extreme, and the water is apt to be so cold as to do harm rather than good. It is important to see that the water is at such a temperature which will bring about a marked reaction. Water colder than this is certainly not beneficial.

That part of Dr. Freeman's paper which interested me most, was what he had to say concerning heliotherapy. Were it not for the photographs of

actual patients which Dr. Rollier has shown and from the accounts of patients who have been at Leysin, none of us, I think, would be inclined to believe the statements of the remarkable cures of tuberculosis which he has brought about. It is well to remember that, although this method of treatment has certainly been neglected in the past, and should be used infinitely more than it is here in this country, we cannot expect, under these conditions, the brilliant cures which Dr. Rollier has obtained. The climatic conditions here are too different. Not only is the amount of actual sunlight infinitely less, but the air is far denser and more moist. We must not forget that there are many, many factors involved in the cure of that most chronic of all diseases, tuberculosis. Heliotherapy will prove a valuable agent, but in using it we must not forget older and well tried methods.

Dr. Freeman spoke of two cases of tuberculous dactylitis in which he obtained remarkable results with heliotherapy after other methods had failed. At my clinic at the Massachusetts General Hospital, I have two young boys of four and six years, brothers, each of whom has a tuberculous dactylitis. These boys live at a considerable distance, in New Hampshire. They certainly do not come often enough for the tuberculin which I have given them to be an appreciable factor. They have not been under close enough supervision for me to carry out heliotherapy, and the hygienic advice which I have given them has involved nothing more than ordinary decent living. They both, however, have been apparently entirely cured under a few months of this regime. In other cases of tuberculous cervical adenitis in which Dr. Freeman stated that he had excellent results, I would call your attention to the figures of Dr. Freeman's fellow-townsmen, Dr. Dowd of New York, who has reported a series of cases of this condition in which he has had unbelievably good results from the so-called radical operation. In my own clinic at the Massachusetts General Hospital during the past five or six years, I can show a fairly large series of most excellent results which I can attribute only to the use of tuberculin, conservative surgery, and good hygiene.

I am very glad, however, that Dr. Freeman has emphasized the value of heliotherapy, and feel that it will distinctly increase our armament in combating this disease.

DR. F. B. TALBOT: I was very much pleased to hear Dr. Freeman's paper and I have been interested in every word that he has said. At the Massachusetts General Hospital we have a very small, dark and dirty ward. Late each spring, this ward is moved out into tents by a street which is noisy and dusty and dirty. The principal difference in the two wards is that one is out of doors and the other is indoors. We have been very much surprised to see how well the babies do in the tents, out of doors. Our only trouble has been with the very poorly nourished babies during the cold nights, when it is sometimes difficult to keep them warm. I was particularly interested in what Dr. Freeman said about the use of water. I believe that one of the most serious conditions that we have to deal with in children who are vomiting or who are having diarrhea is desiccation of the tissues. When the tissue juices get concentrated, the normal functions of the body cannot act in a normal way and many children, I believe, have died merely because they have not had enough water.

DR. FREEMAN (replying to Dr. Place): They are all improved by fresh air, if it is not dusty air. I think that those children should be kept out of strong wind and dusty out-of-door air in stormy weather—they can be out any day excepting a blustery, dusty, dirty day. I think the out-of-door treatment always improves them.

DR. F. P. DENNY: I should like to ask Dr. Freeman how much in heliotherapy is to be attributed to the bronzing of the skin from the effects of the sun and how much to the exposure of the body to cold air. It seems to me we have two very radical things and it is hard to decide which is the more important. There certainly must be a great loss of heat in those children with their bodies exposed.

DR. MAYNARD LADD: May I ask Dr. Freeman if his mortality of 14% in bronchopneumonia at the Roosevelt Hospital included the bronchopneumonias which are so frequently secondary to diphtheria, pertussis, scarlet fever, etc.; and whether such cases were admitted to the hospital?

DR. FREEMAN: In regard to the first question, I imagine that the advantage of heliotherapy is in the sun's rays. Those who are in favor of this treatment like to see the skin well tanned, as they seem to get better results where the skin is well tanned. Whether this is important or not, I do not know.

In reply to the second question, I would say that few of those cases were complicating the communicable diseases, because we will not take these cases into the hospital if we know it, for fear they may spread the disease in the wards.

Book Reviews.

Alveolodental Pyorrhea. By CHARLES C. BASS, M.D., and FOSTER M. JONES, M.D. Philadelphia and London: W. B. Saunders Company, 1915.

The variety of literature, which within the past ten years has appeared on the subject of pyorrhea alveolaris, and the variety of names which has been given to this important condition, are evidence that the disease is thus far not completely understood nor its prevention and treatment fully determined. The present monograph, like others that have been reviewed in previous issues of the JOURNAL, attacks the subject from a new standpoint, regarding the disease as a specific infection by the entameba buccalis. The history, etiology and pathology of the condition are successively discussed, and its symptomatology, diagnosis, treatment and prophylaxis outlined. Essentially the prophylaxis depends on the avoidance of trauma to the gums and the daily rinsing of the mouth with a solution of fluid extract of ipecac or of emetin. Whether or no the conclusions reached by the authors are definitive, time alone will determine, but in any event the work seems a valuable contribution to the study of the subject. It is well illustrated with forty-two figures in the text.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, AUGUST 19, 1915

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*

GEORGE G. SMITH, M.D., *Assistant Editor.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States; \$6.50 per year for all foreign countries by forwarding to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Saturday, from one to two-thirty p.m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

THE ILLNESS OF SIR WALTER SCOTT

In the issue of the *Edinburgh Review* for January, 1913, appears an interesting discussion by the librarian of the Royal College of Surgeons of the illness of Sir Walter Scott, which the author himself describes as gastric cramp, but which at the time was diagnosed as gall-stones. This article is written in conjunction with the publication of the Scott-Baillie letters, which were first given to the public at that time.

Dr. Matthew Baillie, for many years Scott's private physician, is described as a model of this type, one of the finest of a bygone school. In August, 1818, while in attendance on King George III at Windsor Castle, Dr. Baillie beguiled his leisure by writing his personal memoirs, in which he speaks particularly of his lifelong friendship with Sir Walter. Baillie died in 1823, of what was then called consumption, though from the description of his symptoms it seems much more likely to have been malignant disease.

Of Scott's illness we read at length in Lockhart's familiar biography. It manifested itself first acutely on the night of March 5, 1817; and in February, 1819, Sir Walter suffered from so severe an attack of pain that his immediate death was expected. Among the Scott-Baillie letters from the collection in the Library of the Royal College of Surgeons, to which they were presented by Dr. Baillie's son, is the following joint communication to Mrs. Baillie by Scott and his daughter, later Mrs. Lockhart. This letter, recently first published in the *Edinburgh Review*, and reprinted in the issue of the *British Medical Journal* of February 8, 1913, apart from its literary interest, constitutes a piece of valuable clinical symptomatic evidence of the nature of Scott's malady:—

"My dear Mrs. Baillie

I am sorry to be obliged to give you a very poor account of Papa's health, the spasms never leaving him for more than twenty-four hours at a time. We took the liberty of making Doctor Clarkson who attends him here write his ease to your brother (Dr. Matthew Baillie) to request his advice. Papa would have wrote himself, but he has not been able to write for some time, for he has really been dangerously ill and is still very very weak, and is so very much disheartened with the constant return of the spasms that he is quite miserable, but we are in great hopes that the spasms are not so dreadfully violent these two last days. That is the only thing that comforts us. He sends you a letter from Mrs. Siddons (daughter-in-law of Sarah Siddons) he ought to have sent you long ago, but he has been so ill that he quite forgot it.

Dear Miss Baillie, I hope soon to be able to write you a better account of Papa than I can do at present and I hope that you will excuse the shortness of this letter, but I have so few minutes to spare from attending Papa and so tired from being up almost every night that I must conclude with subscribing myself in haste

Very affectionately yours

CHARLOTTE SOPHIA SCOTT.

Abbotsford, Friday 26th, 1819.

(The following is in Sir Walter's handwriting:)

Turn over

Dearest friend

I cannot let Sophia's dolorous epistle go without adding two lines to say that I think I am now getting really better. The combat between the medicines and the disease having been carried on entirely at the expence of my body corporate I feel after so long and obstinate a conflict as I suppose the town of Saragossa did when it had been so desperately attacked and defended. I have no apprehension of any great danger, but till of late the agony was intolerable and lasted six, seven, and eight hours without in-

termission. The fever is now much milder. I have reason to thank God for placing me in circumstances so much above my deserts in every respect and am much too grateful for the blessings which have attached themselves to me in every respect than disposed to murmur under the natural evils of humanity. Kind love, my dear friend, to your sister, Mrs. Baillie, the Dr., and believe me always, well or ill, most affectionately yours
W. S.

My hours have been divided betwixt pain and stupidity."

In April, 1819, Scott again suffered from a violent attack of pain and again believed himself about to die; but upon the amelioration of his symptoms, he sent the following letter to Dr. Baillie describing his experience:—

"Dear Sir,

The Greeks were, I believe, allowed to consult Esculapius by proxy while they were patients, but on recovery were expected to pay their grateful thanks in person. I need not say how much I was obliged by your kind attention to Mr. Clarkson's letter, which gave us all much confidence, which in the extremity of pain and subsequent exhaustion I really could not have drawn from less authority than yours.

The quantity of opium and anodynes of all kinds, I was obliged to swallow during these paroxysms, often with little effect, was truly frightful. But, thank God, the last returns of the pain have been of a description so mild as to yield to the hot bath alone. I begin to sleep at nights, and crawl out on my pony by day, and my bowels seem to be regaining their natural state. I had hoped to have seen you, Mrs. Baillie, and my excellent friends your sisters this spring, but that is now impossible. Some time in the year, however, I may come up for the purpose of getting my son settled in the army.

Believe me, my dear sir,

Very sincerely,

Your obliged and grateful servant,

(Signed)

WALTER SCOTT.

Abbotsford, 17th April."

Throughout the remainder of his life, Scott continued to be afflicted periodically by these paroxysms of pain, presumably due to gall-stones, and indeed performed a large amount of literary work during periods of actual suffering. "The Bride of Lammermoor," in particular, was dictated during the intervals of mental activity following the administration of opium for these attacks. In his "Memories of Sir Walter Scott," edited by Mr. Basil Thompson, Mr. James Skene, a friend of the novelist, gives the following description of the latter's illness, which again presents valuable and vivid primary evidence of the nature of his attacks:—

"Under the infliction of a severe illness, Sir

Walter had for nearly two years to struggle for his life, and only the natural strength of his constitution at length enabled him to throw it off. But with its disappearance, although he was restored to health, disappeared also much of his former vigour of body, activity, and power of undergoing fatigue, while in personal appearance he had advanced twenty years in the downward course of life; his hair had become scanty and bleached to pure white, the fire of his eye was quenched, his step was more uncertain—he had lost the vigorous swinging gate with which he used to move—in fact, old age had by many years anticipated its usual progress, and had marked how severely he had suffered. The complaint, that of gall-stones, caused extreme bodily suffering. During his severest attack he had been alone at Abbotsford with his daughter Sophia before her marriage to Mr. Lockhart, and had sent to say that he was desirous I should come to him, which I did, remaining for ten days, till the attack had subsided. During the course of it, the extreme violence of the pain and spasmodic contractions of the muscles of the stomach were such at times that we scarcely expected that his powers of endurance could sustain him through the trial, and so much was he exhausted by some of the attacks as to leave us in frightful alarm as to what the result had actually been. One night I shall not soon forget; he had been frequently and severely ill during the day, and in the middle of the night I was summoned to his room where his daughter was, already standing at his bedside, the picture of deep despair. The attack seemed to be intense, and we followed the directions left by the physician to assuage the pain, which for nearly a full hour bid defiance to our best endeavours. At length it seemed to subside, and he fell back exhausted on the pillows; his eyes were closed, and his countenance wan and livid. Apparently with corresponding misgivings, his daughter at one side of the bed and I at the other gazed for some time intently and in silence on his countenance, and then glanced with anxious inquiring looks at each other, till at length I placed my fingers on his pulse, to ascertain whether it had actually ceased to throb. I shall never forget the sudden beam which brightened his daughter's countenance, and for a moment dispelled the intense expression of anxiety which had for some time overspread it, when Sir Walter, aware of my feeling his pulse, and the probable purpose, whispered with a faint voice, but without opening his eyes, 'I am not yet gone.' After a time he recovered, and gave us a proof of the mastery of his mind over the sufferings of the body. 'Do you recollect,' he said to me, 'a small round turret near the gate of the Monastery of Aberbrothwick and placed so as to overhang the street?' Upon answering that I did perfectly, and that a picturesque little morsel it was, he said: 'Well, I was there when a mob had assembled, excited by some purpose which I do not recollect; but, failing in their original purpose, they took un-

brage at the venerable little emblem of aristocracy which still bore its weather-stained head so conspicuously aloft, and, resolving to level it with the dust, they got a stout hawser from a vessel in the adjoining harbour, which a sailor lad, climbing up, coiled around the body of the little turret, and the rabble, seizing the rope by both ends, tugged and pulled, and laboured long to strangle and overthrow the poor old turret, but in vain, for it withstood all their endeavours. Now that is exactly the condition of my poor stomach. There is a rope twisted round it, and the malicious devils are straining and tugging at it, and faith, I could almost think that I sometimes hear them shouting and cheering each other to their task, and when they are at it I always have the little turret and its tormentors before my eyes."

It is pathetic to realize that, less than a century ago, the later years of one of the world's greatest geniuses were tormented by a malady that modern surgery would easily and safely relieve. That in spite of this affliction he accomplished the enormous and brilliant literary labor of that period of his life remains, perhaps, one of the best evidences of the transcendence of his intellectual powers.

DE-ALCOHOLIZATION OF BEVERAGES AS A PREVENTIVE OF INEBRIETY.

IN another column of this issue of the JOURNAL we publish an article by Dr. Irwin H. Neff on "The Practical Treatment of Inebriety" based on his experience at the Norfolk State Hospital. Since the establishment of such institutions devoted solely to the treatment of alcoholic inebriates, it is noteworthy that the improvement obtained in this class of cases by the application of special methods and by segregation has been more marked, rapid and permanent than when these patients were mixed with the inmates of other state institutions.

However great the progress of recent years in the treatment of alcoholism, it is nevertheless to be recognized that beyond, and far more important than, the treatment of the individual inebriate is the prevention of inebriety in the community. This problem for which so many different solutions have been suggested and attempted,—by prohibition, by restriction, by popular education,—must be regarded as still lying far from an adequate settlement. It remains, in fact, one of the greatest present prob-

lems of civilization. One may doubt even whether the reported decline in the consumption of alcoholic beverages among certain of the beligerent European countries either is as extensive as alleged or will continue under the conditions that must follow the cessation of hostilities.

As a matter of fact, perhaps the greatest shortcoming of all methods aimed at the prevention of inebriety is their failure to supply any adequate gustatory substitute for the great variety of pleasant alcoholic beverages to which mankind has so long been accustomed. Doubtless a certain proportion of drinkers consume these beverages solely for the sake of their stimulative effect. It seems probable, however, that a considerable number of persons, especially the moderate and convivial drinkers, whose motives are largely social and aesthetic, drink chiefly on account of the agreeable taste of the beverage which they consume. Now the suggestion has recently been made that for drinkers of this latter class, who are chiefly of the more intelligent type and would be quite willing to give up the stimulus of alcohol, a large number of agreeable substitutes for alcoholic drinks might be provided by the de-alcoholization of beers and wines, a process whereby the alcohol is almost entirely removed and the taste not affected.

The process of de-alcoholization, as described in an article by Mr. O. Overbeck, F.C.S., F.G.S., in the issue of the *Medical Press and Circular* for July, 1914, consists in blowing through the fermented liquor, at a temperature lower than that of the human body and in a suitably constructed plant, the waste gas produced during fermentation. This procedure leaves the resultant liquid unaltered in every respect, except for the removal of its alcohol, and may be continued until the alcohol is entirely removed, or may be checked at a point where the beverage contains only 1% or 2% of alcohol, the amount commonly found in fermented ginger beer and other so-called temperance beverages. The use of the waste gas of fermentation is adopted as a measure of economy; but carbonic acid gas from any other source, or indeed any neutral gas such as nitrogen, may be employed with the same effect.

Samples of beers and wine de-alcoholized by this method have been analytically and critically examined by the British government, which has found that the alcohol had been truly abstracted from these beverages, that it was not reproduced on keeping, and that the beverage itself was in

each case as brilliant and palatable as the alcoholic original.

"Wines of all descriptions, whether sparkling or still, can be de-alcoholized and yet sold in their ordinary state, the difference in flavour being almost imperceptible. In the case of very highly alcoholic wines, such as old port or sherry, the only effect is to lower slightly their somewhat spiritous taste. Perhaps the most marvelous effect accomplished by this process is the complete sterilization of the resulting liquid. After fifteen months a beer de-alcoholized to half the strength of ginger beer was found absolutely identical in spirit content, although no preservative whatever had been added. This is explained by the mechanical violence of the action of the gas as it is passed through. The CO₂ is driven through the circulating system with such violence that, not only is the whole of the liquid converted into a mass of froth whilst the action is taking place, but the delicate yeast cells, to which fermentation is due, become ruptured and killed. It is also probable that many superficial spores and cells are blown away by the gas in the form of microscopic dust from the thin sides of the fine bubbles produced. This process when continued for two hours and a half is sufficient completely to sterilize the liquid. It also carries away such other spores as may be present, into the large volume of water containing the preservative agent through which the gas has to pass in order to be deprived of its alcohol before it undertakes its next career through the liquid which is being acted upon."

If these statements be true it would appear that a method has been devised whereby a large number of alcoholic beverages may at once be deprived of the alcoholic content which makes them injurious and at the same time remain as palatable and attractive as before. Whether or not the de-alcoholization of high proof spirits is also possible remains to be determined. In any event the employment of de-alcoholized wines and beers as beverages would seem to be a possibility of definite value as a preventive of alcoholic inebriety.

ENLISTMENT OF CONSUMPTIVES.

THE problem of whether or not to recruit men who have had tuberculosis does not now present any great urgency to the United States Army medical officers, but it may do so at any time.

Of course there can be but little dissension when the general statement is made that candidates suffering from an active pulmonary condition should not be enlisted, no matter what the exigencies of the situation, but in regard to the so-called cured patients there must exist more difference of opinion.

Dr. L. Thieme, medical superintendent of the Leipzig Sanatorium in Voightland, published his views on this subject in the *Muenchener medizinische Wochenschrift* for March 16, 1915. By consulting the military records he found that 241 of his former patients were in the German army. These, presumably, had not been recognized as such by the recruiting officers, for the latter had rejected 621 of his former patients. Dr. Thieme states that these 241 represent about one-fifth of all his discharged male patients of military age and concludes therefrom that his sanatorium treatment is highly successful.

We are inclined to think, however, that this deduction is somewhat premature and a little too optimistic. It is quite conceivable that many of these phthisical soldiers will break down eventually under the rigors of the present war. In fact, Dr. Thieme admits that 28 of his former patients were accepted at first but broke down later.

Military life with all its stress and strain, especially when a country is at war, will hardly appeal to medical men as a proper occupation for consumptives who have at one time been sufficiently affected to require sanatorium treatment. There must also be considered the danger of contagion in a crowded camp, should the disease process again become active. Considering the immense population which this country could draw from in case of war, it would seem that recruiting officers would be justified, even in a great national emergency, in refusing applicants who had suffered from tuberculosis.

SANITARY CONDITIONS OF BOSTON STREETS.

WITH the movement on foot to improve the paving of the streets of Boston a good opportunity arises also to do something to improve the sanitary conditions at the same time. No better demonstration is needed than to walk through our streets on a windy day. Dr. Sachs of New

York, in a lecture before the Academy of Medicine brought out some very pertinent facts in regard to the relation of the medical profession to street conditions. While his remarks were directed to conditions in New York, they may apply just as well to Boston.

As a city like Boston grows in population, special problems arise, and if we cannot lead, we can at least profit by results worked out for the public good in other cities. In regard to street conditions there seems to be a feeling of indifference. This may be due to the fact that the problem is divided between a number of departments. Nevertheless the streets cannot be kept clean unless all coöperate. Dustless sweeping should be enforced not only of the roadway but of the sidewalk. To walk down town on any of our main streets, even at 8.30 a.m., on a pleasant day means getting dust in the eyes, nose and mouth. The sidewalk in many sections is worse than the street. We cannot get rid of dirt entirely, but it can be minimized. The open garbage can in the alley is another menace. In warm weather it is a fly and disease breeder. It would seem that no argument should be needed to sustain the proposition that all garbage cans and wagons should be covered.

The street department often has to bear the blame of conditions for which it is not directly responsible but because its work is hampered by various influences. Blocking of streets by building material, destruction and obstruction of highways by public service corporations, impair efficiency and discipline among the employees of the cleaning and repairing departments.

Dr. Sachs shows that in one of the most congested districts of New York City, the East 5th street police district, where the health, police and street departments work together, the streets on a busy day were found to be in a high state of cleanliness. Sooner or later the public must think of this problem and the medical man will be called on for advice in order that best results with most economy may be obtained.

MEDICAL NOTES.

HOT WEATHER AND THE CITY'S HEALTH.—Figures issued by the New York Department of Health on July 31 showed that despite the hot weather of the past week, the death rate was .12 of a point lower than for the corresponding week of last year. This decrease in rate is equivalent to a saving of 13 lives. As compared with the

previous week, there was an increase of 29 deaths caused by the greater number of deaths from diarrheal diseases under five years. As might be expected, the deaths of infants under five years of age showed a rather sharp increase. The deaths of persons over 65 years, however, showed a very marked increase. The total for the 31 weeks of 1915 is 13.50 as compared with 14.28 for the same period of 1914. There were 1328 deaths in the City of New York during the past week with a corresponding rate of 11.94. The lowest rate was seen in the Borough of Richmond; the highest in the Borough of The Bronx.

HONORARY DEGREES TO PHYSICIANS.—The University of Edinburgh has recently conferred the honorary degree of LL.D. on Dr. W. A. Herdman, professor of zoölogy in the University of Liverpool, and on Dr. Arthur Thompson, professor of anatomy at the University of Oxford.

AWARD OF MEDALS FOR SCIENTIFIC EXHIBITS.—The following award of gold medals is announced for scientific exhibits at San Francisco:—

“To the pathological departments of Stanford University and the University of Michigan; to the Indiana State Board of Health, for its exhibit on a public health campaign; to Drs. C. C. Bass and F. M. Johns, of Tulane University, for their exhibit on pyorrhea alveolaris and malaria; to Drs. Claud A. Smith and J. Witherspoon, on hookworm; to the pathological laboratory of the New York Lying-in Hospital, on the demonstration of the cultivation of human tissue *in vitro*; to Dr. Martin H. Fischer, of Cincinnati, on newer experiments in the physiology and pathology of kidney functions; and to Dr. J. T. Case, of Battle Creek, on lantern slides illustrating Roentgen-ray studies.”

SMALLPOX CASE IN PLAINFIELD.—Report from Plainfield, N. J., states that a death from virulent smallpox occurred in that city on Aug. 5, the patient being a man brought that morning to the city from Metuchen. Extensive vaccination and quarantine of contacts has been instituted.

PREVALENCE OF MALARIA, MENINGITIS, PELLAGRA, POLIOMYELITIS, SMALLPOX AND TYPHOID.—The weekly report of the United States Public Health Service for July 30, notes that during the month of June, 1915, there were reported 19 cases of cerebrospinal meningitis in Massachusetts; and in Mississippi, 5 cases of meningitis, 10,703 of malaria, 3,195 of pellagra, 7 of poliomyelitis and 536 of typhoid fever. During the same month there were in Ohio also 7 cases of poliomyelitis, 356 of smallpox, and 242 of typhoid. There were 103 cases of typhoid in Massachusetts and 220 in South Carolina.

PLAGUE IN ASIATIC COUNTRIES.—During the period from March 26 to May 20, 1915, there

were reported in Java 582 cases of bubonic plague, with 521 deaths; in Kuaehi, India, 464 cases with 386 deaths between May 2 and June 5; and in Bagdad, from May 2 to 15, 418 cases with 293 deaths.

DEPARTMENT OF HEALTH, BUFFALO, N.Y.—The recently published report of the Department of Health of the city of Buffalo, N.Y., for the year ending December 31, 1914, is presented in a pamphlet of 230 pages with numerous tables of statistics and pictures of the infant welfare stations, dental dispensaries and tuberculosis schools. The organization of the department of health of that city consists of Francis E. Fronczak, M.D., as health commissioner, an assistant health commissioner, and 242 members of the following bureaus and divisions: bureau of vital statistics, of plumbing and drainage, of chemistry, of bacteriology, of sanitation, of food and drugs, of hospitals, of child hygiene, and the psychopathic bureau. The bureau of child hygiene includes the divisions of infant welfare, midwifery, children's institutions, medical and dental school inspection, and child labor. The total death rate for the city was 15.50 per thousand and the birth rate 27.77 per thousand. The principal cause of death was pulmonary tuberculosis, the total number dying from this cause being 633. The total number of deaths from communicable diseases was 1,172. One thousand five hundred and thirty-three children died under one year, of which number 439 died from diarrhea and enteritis. Four hundred and forty-four deaths were due to violence. As an exhaustive record of the very efficient health department administration of this city, the report is interesting and commendable.

FOOT AND MOUTH DISEASE IN ILLINOIS.—Report from Chicago on Aug. 9 states that several new cases of foot and mouth disease have been discovered among livestock in Wheeling, Ill. A five-mile quarantine district has in consequence been established about that town.

EUROPEAN WAR NOTES.

CHOLERA AND TYPHUS FEVERS IN AUSTRIA.—Report from Vienna, by way of Zurich and London, states that on Aug. 4 the total number of cases of Asiatic cholera in the Austrian Empire amounted to 629. From April 25 to May 8 there were reported 645 cases of typhus fever in Austria, mainly among soldiers, prisoners of war, and persons from Galicia.

A NEW ANTISEPTIC MIXTURE.—A press report from Paris on Aug. 5 states that Professor Landouzy has recently announced to the French Academy of Science that Dr. Alexis Carrel and Dr. Henry D. Dakin, of the Compiègne military hospital have used with great efficacy in the treatment of infected wounds an antiseptic mix-

ture of hypochlorite and carbonate of lime and boric acid. Future scientific confirmation of the value of this reported discovery will be awaited with especial interest.

RELATIVE DEATH-RATES OF GERMAN WOUNDED.

—In last week's issue of the JOURNAL we published a statement from the *Lancet* relative to the high death-rate prevailing among British wounded in the war. In the issue of the *Berliner Tageblatt* for July 10 appears the following tabulated statement of the relative death and recovery rates among the German wounded:—

1914.	Returned to Service.	Deaths.	Recovered But Unfit.
August	84.8	3.0	12.2
September	88.1	2.7	9.1
October	88.9	2.4	8.7
November	87.3	2.1	10.6
December	87.8	1.7	10.5
1915.			
January	88.7	1.4	9.9
February	88.6	1.3	10.0
March	88.9	1.6	9.5
April	91.1	1.4	7.4
Average	88.5	1.9	9.6

STANDING OF THE AMERICAN RELIEF FUNDS.—On Aug. 10 the totals of the principal American relief funds for the European War reached the following amounts:—

	N. Y.	N. E.
Red Cross Fund.....	\$516,454.31	
Committee of Mercy.....	252,069.14	
Serbian Fund.....	120,542.56	
Polish Fund.....	54,400.75	\$49,578.05
Persian Fund.....	40,695.52	
St. George's Fund.....		10,823.44

BOSTON AND NEW ENGLAND.

MILK AND BABY HYGIENE ASSOCIATION.—It is reported that during the month of July, 1915, the Boston Milk and Baby Hygiene Association cared for 1960 babies in this city. The following physicians have been appointed in charge of the free clinics for well babies:—

Dr. Richard S. Eustis, Dr. John W. Hammond, Dr. Harry L. Rothblatt, Dr. W. W. Barker, Dr. Harold A. Gale, Dr. William W. Howell, Dr. Arthur B. Emmons, 2nd, Dr. Orville Chadwell, Dr. James K. Wardwell, Dr. K. G. Percy, Dr. Edwin T. Wyman, Dr. Mitchell Sisson, Dr. S. M. Pearl, Dr. S. W. Cornish, Dr. C. R. Draper, Dr. H. A. Durkin, Dr. H. Howard Flagg, Dr. Benjamin Friedman, Dr. Joseph I. Grover, Dr. Margaret Grogan, Dr. Lewis J. Hill, Dr. F. J. Larned, Dr. Z. R. Scott, Dr. Louis S. Silver.

HAEMORRHAGIC CATTLE SEPTICAEMIA IN BOSTON.—It is announced that two fatal cases of haemorrhagic septicaemia among cattle in Bol-

ton, Mass., have recently been reported to the State Bureau of Animal Industry. Steps have been taken to prevent the spread of the disease.

EDUCATIONAL WORK OF THE STATE DEPARTMENT OF HEALTH.—The State Department of Health has announced that it is prepared to supply free of charge moving picture films portraying lessons in general health and hygiene such as the dangers of unsanitary living conditions, typhoid fever, neglect in the care of children. A lecturer will accompany the films and explain them. It is hoped that schools and other organizations will be interested in this way to carry out the plans of the department of health to educate adults, as well as children, in matters of general hygiene.

FUMIGATION AS A METHOD OF DESTROYING BACTERIA DISCONTINUED.—It is reported that the Boston Board of Health, through its chairman, has announced its abandonment of the practice of fumigating rooms which have been occupied by patients with contagious diseases such as diphtheria and scarlet fever. In the belief that such germs are soon destroyed by light and air and are not transmitted by inanimate objects, making fumigation useless and wasteful, the Board of Health believes that emphasis should be placed on the prevention of contagion through convalescents, whose bodies offer a congenial host for bacteria and who, in spite of repeated negative tests, often prove to be unsuspected carriers of the disease from which they have recovered.

MEETING OF THE MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH.—At a meeting of the Massachusetts Association of Boards of Health at Pemberton, Mass., the subject of the control of tuberculosis was discussed from its legal side. A paper written by the late Chester Bryant, of the Haverhill Board of Health, urged the passage of laws providing boards of health with proper power to control the inconvertible consumptive. A committee was voted for, to arrange a more uniform system of departmental monthly and annual reports.

VALUE OF PUBLIC HEALTH NURSES.—In an interview published recently in the Boston daily press, Prof. Selskar M. Gunn, director of the recently established division of hygiene of the Massachusetts State Health Commission, is quoted as follows regarding the value of public health nurses in the community:—

"Of all the public agencies for saving life in Massachusetts, the most important is the public health or educational nurse. I have come to this opinion after a thorough analysis of the death rate and its causes in every town of the Commonwealth. Any community can lower its death rate by employing public health nurses.

"No community of any size can hold up its

head unless it maintains a nurse to advise and help the mothers save their babies from the dangers of hot weather, heavy clothing, bottle feeding and dirty milk, indigestible food, bad ventilation, filth, flies and general ignorance of the needs of sanitary precaution. So many of the diseases of babies are preventable that the infant mortality rate is the sanitary index of the community.

"In Massachusetts the death rate should be greatly lowered in the next year. Of 53,286 deaths in this state in the last year, for which we have reliable statistics, 9,971 were of babies less than a year and a half old and nearly half were victims of preventable disease. Summer diarrhea carried off 2,682, pneumonia 1,597, whooping cough 168, measles 156, and tuberculosis 180. Under ideal conditions these deaths could have been prevented. In the same year diphtheria claimed only 41 and scarlet fever only 14 under one year old.

"One-fifth of all deaths in Massachusetts, however, are deaths of infants. The first year is the critical year. That the second summer is the most dangerous one is a fallacy. In the state statistics before me, I find that when summer diarrhea carried off 2,682 babies under a year old, only 395 died between the ages of one and two. The only diseases that show a greater mortality in the second year than in the first are measles and whooping cough. A mother greatly minimizes the danger from these two diseases if she protects her children from them during the first five years of childhood.

"It is evident, therefore, that the surest way to lower the state death rate is by saving the infants. In this work the nurse is, in my opinion, about five times as effective as the sanitary inspector. He gets into the shops and the back yards. The nurse gets inside the mother's heart.

"The city of Boston employs fourteen public health nurses. Their work is supplemented by that of nurses supported by numerous private and semi-public institutions and by milk and hygiene stations. In some Massachusetts towns women's clubs are paying the public health nurse. Too many towns and cities have not yet begun to realize the great value of her service."

Miscellany.

MEDICAL FEES IN THE SIXTEENTH CENTURY.

IN the issue of the *Lancet* for June 5 is published a series of extracts from the household account books preserved at Belvoir Castle among the historic documents belonging to the Duke of Rutland, ranging in date from 1522 to 1700. These accounts not only throw light on local and family history, social customs, man-

ners of living and cost of food, drink and costume, but contain also numerous charges for medical attendance, indicating the range of fees charged in a wealthy noble family during the sixteenth century. The following are a few examples of these payments recorded to physicians and apothecaries and other items of more or less direct or remote medical interest.

“1528.—Payde, be my Lorde's comaundement, to Doctor Freman, fysicion, xls.

1530.—Item, to Doctor Freman, fusician, xs.—To Doctor Freman, fusician, for his paynes with my Lorde Ros, xxc. Item, to Doctor Bartlott, by my Lorde's commaundement, vjs, vjd.—Item, to Peerson the poticary for divers restoretyffes, vjs, iiijd.

1532.—Item, geven in rewarde to the myddewif and norys at the christenyng of Master Hervie's childe, xxs.

1533.—Item in reward, the xij day of *Julii*, to Roger Smyth poticarye, for his paynes, takyn with my Lord in his fevir, vijli, xiijs, iiijd; to him for such stuff as he spent about my Lord in the tyme of his sekeness, xxxijs, xd.—Item in reward at the same tyme to Doctor Bartlet, xxxs.—Item in reward to Doctor Freman the same tyme, xiijs, iiijd.—Item to a woman phicisian at Bingham in the Vale, iijs, vjd.—Item to Roger Smyth, poticary, for my doughter Anne, iijs, iiijd.

1536.—Item to Doctor Clement for looking to my Lorde Roos when he was seke at Endfylde, xxxs.—Item to the same doctor at another tyme at Yorke Place, xs.

1537.—Item in reward to Master John the poticary for ij glasses of oyle of almons and for a medecin for my Lorde's childern for the wormes at ij tymes, xs, xd.

1540.—Paide in reward to Doctor Bill comynge to my Lord at Halywel, xxs.—Item payd to Doctor Edwardes for his reward, beyng with my Lord Roos at Croxton in his sekeness, and for his costes goyng to Cambrige for six days at vjs, viiijd, the day, iiijli.

1541.—Item, the xxvijth day of February, to Mr. Leveret, the phisicion, for that he came to my Lady then and tarried at Belvoier iiij days, xs.—Item, gyven in rewarde to Mr. Edwardes, phisicion, of Newarke, for his comyng to se Maistres Margaret Paston when she was seke, vs.—Item, gyven in reward to Mr. Leverett for mynstryng medecyns to my Lord Rose when he was seke, xs; and for the like mynstryng to Maistres Margaret Paston in her sekeness, xxijs, vjd.—Item, payd for a pynte of aquawyte, xijd.

1542.—Geyvn to Doctor Augustyne at diverse tymes (over and beside iiijli, xs, in the price of a gowne of damask lxxxs.—Geyvn to Doctor Buttes, xxijs, vjd.—Geyvn to Doctor Nicholas at diverse tymes, vijli, xs, xd.—Geyvn to Doctor Crome at diverse tymes (over and beside xj yardes of damask for a gowne, price iiijli, xs), lxxvijs, xjd.—Geyvn to Doctor Bill at ij tymes, xls.—Geyvn to Mr. Oliff, the

Kinge's surgian, at diverse tymes (over and beside xj yardes of damask for a gowne, price iiijli, ljs, vjd), vijli, xiijs, vjd.—Paid by Anthony Digby for ypoeras when my Lorde was syke, vjs, viiijd.

1543. (Account of the executors of the will of Thomas, Earl of Rutland re funeral expenses, &c.)—For the charges of the stufe that was occupied about the searing of the corps, and to the surgion for his penes, as apperithe by Thomas Disney's booke, xiijs; to the plummer for putting the corps in lead, iijs, iiijd; to Doctor Wendy for his paynes takyng about the seid Erle in his siknes and after, contyneyng there by the space of ij days, vijli, iijs, xd.

1551.—Item to Doctour Wotton for his consaile in phisik to my Lord, xs.—Item to Goldring the potecary for marmalad and other things, xs.

1554.—Item to Docter Hyll, xxs.—Item to Doctor Wooton, the same daie, xs.—Item to Holland the surgion, the same daie, iijs, iiijd.

1555.—Item in reward to John Rolpotey, my Lord's surgion, by his commaund, xls.—Item, by my Lorde's commaund, to the straunger that ys his surgion, xs.

1558.—Item to Doctor Peter and Doctor Hil at ij several times for their coming to my Lady, xxvjs, viiijd.

1559.—Item paid for eariage of Bukston's water sent to my Lord of Penbrok, iijs, iiijd.

1590.—Item geven at the christenyng of Mr. Basette's daughter, to myddewif and nurse, xxs.

1594.—Paid to Mr. Docter Hunton and Mr. Harry Webster for comynge to Belvoyre to her Ladyship, xxxs.—Paid to George Sandwith, barber, for comynge to Belvoyre ij severall tymes to tryme his Lordship, vs.

1598.—Item for two bezer stones, vijli.

1599.—Item geven to Doctour Marbeck for the waters and phisicall thinges sent towards Ireland, and for his paynes in providing them, xli.—Item geven to Mr. Goodrous, her Majeste's sergeant chirurgian, whom she sent to my Lord, vii.—Item geven to Mr. Thorne, chirurgian, vijli, xiijs, iiijd.—Item to Mr. Doctour Marbeck for his half yeares aunytie due at Our Lady Day, iiijli, vjs, viiijd.—Item paid to the apothecary for phisick for Capten Whitlock, xxvjs; and geven to Doctour Marbeck for his paynes about the Capten in his sicknes, by his Lordship's commandment, vii.

1600.—Item in rewarde to Doctour Marbeck for certen waters and other thinges which he bought and provided for my Lordes use in his journey into Holland, and for his paynes, xli.

1604.—Paid to Mr. Docter Hunton in rewarde comynge to my Lady iiijli, and to John Lucas his potticarie, xis.—Paid to Mr. Docter Mumforde for comynge from London to mynister phisicke to mye Ladye, xvi.

1605.—Item, to Mr. Perk for letting his Lordship's blood, xxxs.

1606.—Item, to Sir Walter Raleigh's man that brought a water for my Lord for the col-

lieque, xxs; for half an oz. of muske to make plaister, xxxs; a pounce of tobacco sent to Belvoire, xls; tobacco pipes, vs.

1607.—Given to Mr. Rigesley, of Newarke, phisision, being sent for to come to Henry Lynforde, by my Lord his comaundiment, xxxs.—Given to Mr. Alton, of Nottingham, phisision, as in rewarde for attending of my Lady and mistris at Belvoire, *vli*.

1609.—Item paied to Mr. Doctour Percywaile, apothecary, for viij oz. of elixar of saltt. *iiijli*, *iijs*; water distilled, a quart. *vjs*; pylls. *ijs*, *vjd*.

1611.—Item, for a plaster for the gowte from Mr. Crammer for my Lord, *xs*.

1612.—Item to Mr. Frederick and Mr. Guillian, chirurgians, for their attendance upon my Lord (Roger, Earl of Rutland) at Cambridge from the tyme of Mr. Guillian's comyng to Cambridge and for the incision made, *jli*, and for embalmynge the corps, *xxli*.

1614.—Paid Fredrick, the surgeon, for imbalmyng the corps of Sir Olliver Manners, *xxxli*.

—Delyvered to Mr. Waters, of Stamfordord, when he was sent for to my Lord Roosse, beeing not well, *iiijli*.—Paid the same daie unto John Hilton, his pothecarie's man, for apothecarie stuffe, *iijs*, *iiijd*.—Delyvered to Mr. Doctour Ridgley, of Newark, for ten daies beeing at Belvoire with my Lorde Rosse, *xli*.

1615.—To Doctour Ridgley, for beeing at Gardon with my Lorde Roosse, when he was not well, payd to him for *vj* daies, in goulde, *vjli*, *ijs*.

1618.—Paid to Docteur Anthony for a dram of the essence of gold, *6li*.

1640, August 11th.—Item paid to Sir Daniell Belyne for two gree stones, whose virtue is good to cure the stone in the bladder or kydneyes, for which I (Earl of Rutland) have payd *3li*, *5s*, and am to have a twelv moneths tryall, and yf do not like them I shall have *40s* for them gaine.

1652.—Paid to my honourable Ladye's hands or Docteur Preedian, at twise, for his care of Lord Roosse, *50li*.—Paid Mr. Turnor that preends to cure my Lord, *9li*, *5s*.

One may question whether this last sentence is merely a fashion of phraseology, or whether may perhaps contain some conscious or unconscious irony about Mr. Turnor's services.

PETITION FOR TUBERCULOSIS NURSES.

THE following petition has been presented to the city council of Los Angeles, California, to the end that a sufficient staff of tuberculosis nurses may be provided to further the work of the eradication of tuberculosis in that city. The initiative petition received about 20,000 signatures and passed at the June election by a vote of 47,359 to 25,681.

"To the Honorable, the City Council of the City of Los Angeles, County of Los Angeles, State of California.

"Whereas, New York City, with 165 municipal tuberculosis nurses has recorded a diminution in the number of cases of tuberculosis from 32,065 in 1910 to 22,752 in 1912; and a reduction in the death rate from pulmonary tuberculosis in Manhattan and the Bronx from 427 per hundred thousand in 1881 to 190 per hundred thousand of population in 1912, a reduction of 55%; and

"Whereas, the results obtained in New York City are ascribed largely to the employment of municipal tuberculosis nurses, in a communication from the General Medical Officer of the City of New York, Herman M. Biggs, dated Dec. 18, 1913; and

"Whereas, in the City of Boston, Massachusetts, 'all cases of tuberculosis reported are visited by nurses,—twenty-five in number,—paid by the city, and it is rare there now to find a neglected or abandoned case, and there has been a diminution in the total number of deaths from tuberculosis and also in the case rate'; and

"Whereas, the city of Baltimore, Maryland, with a force of 17 tuberculosis nurses has secured a reduction in both the cases and deaths from tuberculosis, so that the Commissioner of Health of that City declares that their work shows the need of many more tuberculosis nurses; and

"Whereas, the city of Buffalo, New York, with a force of 17 tuberculosis nurses, feels the need of more tuberculosis nurses; and

"Whereas, the city of Cleveland, Ohio, with 15 tuberculosis nurses and a record of good results, declares the need of more tuberculosis nurses; and

"Whereas, the city of Columbus, Ohio, has six tuberculosis nurses; and

"Whereas, the city of Los Angeles, California, has only one tuberculosis nurse and has shown an increase of about 50% in the reported cases of tuberculosis during the past year, and a large increase in the number of deaths from that disease; and

"Whereas, the work in the eastern cities, above referred to, has shown that a visiting tuberculosis nurse cannot satisfactorily take care of more than one hundred cases of tuberculosis; and

"Whereas, a recommendation similar to the following proposed ordinance, received the unanimous endorsement of the Nursing Commission of the city of Los Angeles, Jan. 6, 1914, and has been endorsed by many of the leading business men, firms and organizations paying taxes in the city of Los Angeles; therefore,

"The following ordinance is hereby proposed, to be adopted by the City Council of the city of Los Angeles, or, if the same be not adopted by said Council, the proposed ordinance then to be

submitted to a vote of the electors of the city of Los Angeles as provided in the Sections 198-a, 198-b, 198-c, 198-d, and 198-e of the Chapter of the city of Los Angeles governing the initiative; to wit:—

“An Ordinance Providing for the Employment of Municipal Visiting Tuberculosis Nurses.

“Section 1. The Health Commissioner of the city of Los Angeles shall and is hereby empowered and directed to employ, in the name of and for the city of Los Angeles, municipal visiting tuberculosis nurses, in the proportion of one such nurse per one hundred reported cases of tuberculosis in the City of Los Angeles.

“Sect. 2. The municipal visiting tuberculosis nurses thus employed by the Health Commissioner of the city of Los Angeles, shall be paid by the city of Los Angeles at the rate of compensation provided for Municipal Nurses in Section One of Ordinance No. 28, 179 (New Series).

“Sect. 3. It shall be the duty of the municipal visiting tuberculosis nurses of the city of Los Angeles to visit professionally all reported cases of tuberculosis in the city of Los Angeles, excluding those under treatment in public or private hospitals or sanatoria, unless requested in writing not to do so by the patient or physician in charge.

“Sect. 4. The Health Commissioner of the city of Los Angeles is hereby empowered to establish such supply stations as he may deem necessary from time to time for the professional use of the tuberculosis nurses provided for in this ordinance.

“Sect. 5. The Purchasing Agent of the city of Los Angeles is hereby directed to purchase on requisition from the Health Commissioner such supplies as the latter may from time to time deem necessary for the professional use of the tuberculosis nurses provided for in this ordinance.

“Sect. 6. The Health Commissioner shall divide the city of Los Angeles into appropriate sections or districts and shall assign one or more tuberculosis nurses to each and every section or district thus formed according to the number of cases of tuberculosis therein, exclusive of those under treatment in public or private hospitals or sanatoria.

“The tuberculosis nurses shall be held responsible for their respective sections, but may at the discretion of the Health Commissioner be given work outside of the sections to which they are assigned.

“Now, therefore, we the undersigned qualified electors of the said city of Los Angeles, do hereby petition your honorable body to adopt the said ordinance for the city of Los Angeles, or, if the same be not adopted by council, we hereby demand the submission of the said ordinance to a vote of the qualified electors of the said city of Los Angeles, in accordance with the sections of the city charter of the city of Los Angeles governing the initiative.”

MEDICAL BROTHERHOOD FOR THE FURTHERANCE OF INTERNATIONAL MORALITY.

THE following is the text of the appeal to which we have referred in previous issues of the JOURNAL, which was recently issued by Dr. S. J. Meltzer to the men and women engaged in medical practice and the advancement of the medical sciences.

“The present war among civilized nations has brought out impressively certain facts: that although there are civilized *individual* nations, we are still very far from having a civilized humanity—there is an abyss between *intranational* and *international* morality; that, no matter how cultured and enlightened nations may be, they still settle their international differences by brute force, by maiming and killing their adversaries; and, finally, that the present high development of science and invention in individual nations only serves to make the results of this war more destructive than any other in history.

“The war has demonstrated, however, one encouraging fact, namely, that among all the sciences and professions, the medical sciences and medical practice occupy an almost unique relationship to warfare, and that, among all the citizens of a country at war, medical men and women occupy a peculiar and distinctive position.

“No discovery in medical sciences has been utilized for the purpose of destroying or harming the enemy. Medical men in each of the warring countries are as courageous, as patriotic, as any other citizens, and are as ready to die or to be crippled for life in the service of their country as any other class of their fellow countrymen. Their services, however, consist in ministering to the sick and to the injured and in attending to their sanitary needs. Furthermore, they often risk their lives by venturing into the firing line to bring the injured to places of safety and to attend to their immediate needs. *In these heroic and humanitarian acts friend and foe are treated alike.* Finally, the majority of the members of the medical profession and of the medical journals of the neutral as well as of the warring countries, abstain from public utterances that might be grossly offensive to any of the belligerent nations.

“These facts—this advanced moral position in international relations which medicine and its followers are permitted to occupy in all civilized nations,—ought to be brought to the full consciousness of the men and women engaged in the medical sciences or in medical practice. Such realization could not fail to have an elevating influence upon the medical profession itself, and would probably exert a favorable influence upon the development of international morality generally.

“At the dawn of history, medical men were frequently also the exponents of philosophy and morals. In the middle ages, when knowledge

became specialized, medical men more and more devoted their activity exclusively to medical practice. Because of its inefficiency at that time, medicine lost its prestige. In recent times, however, medicine is becoming an effective science; one marvelous discovery has followed another, and the efficiency of medical practice has been rapidly increasing. Medicine makes habitable to man hitherto uninhabitable parts of the world. It prevents disease; and, with increasing theoretical and practical efficiency, medicine's learning to alleviate and cure disease and injuries. Medical sciences and medical men have steadily risen in the esteem of civilized mankind. *Lay not the medical sciences and medical men become again the standard bearers of morality, specially of international morals?*

"To accomplish these objects, it is proposed to organize as large and effective an Association as may be possible, of men and women engaged in the medical sciences or in medical practice under the name of

THE MEDICAL BROTHERHOOD FOR THE FURTHERANCE OF INTERNATIONAL MORALITY.

"It is obvious that such a Brotherhood could of exercise an important influence at once, but our modest expectation for prompt results would not prevent us from attempting now to take the first step in the right direction. Many important results have often had small beginnings.

"A Committee of Physicians and Medical Investigators request you herewith to enroll as a member, and to declare your willingness to endorse and support the moral standard which the medical profession generally upholds when called upon to perform its patriotic duties in an international strife.

"It should be expressly understood that it is not the object of the proposed Brotherhood to influence the feelings and views of any one regarding the problems involved in the present war. It is desired merely to bring to the full consciousness of the members of the medical profession the exceptional moral position which civilized nations, even while at war, permit and expect medical men to occupy, at least as long as they remain in the medical profession and act in this capacity. This consciousness cannot fail to elevate the moral standards of physicians. Furthermore, after the close of the present war, the Brotherhood could, without doubt, facilitate the reunion of the members of the medical profession of all the nations which are now at war and increase good feelings among them. A humanitarian body, such as the proposed Brotherhood, if already in existence and ready for service, might and could be of the greatest usefulness in many ways."

CONDITIONS OF NAVAL SURGERY IN THE EIGHTEENTH CENTURY.

IN the issue of the JOURNAL for Oct. 22, 1914, we published an article on Dr. Tobias Smollett and some of his experiences as a physician and novelist. In the issue of the JOURNAL for Dec. 17 Dr. William P. Cones called further attention to the description in Roderick Random of Smollett's clinical duties as a naval surgeon. In the issue of the *British Medical Journal* for Feb. 6 appears still further comment on the conditions of the sick sailors in Smollett's time and the details of medical practice as he must have known them:—

"About fifty miserable distempered wretches suspended in rows, so huddled one upon another that not more than 14 inches space was allowed for each with his bed and bedding; and deprived of the light of day as well as of fresh air; breathing nothing but a noisome atmosphere of the morbid steams exhaling from their own excrements and diseased bodies, devoured with vermin, hatched in the filth that surrounded them, and destitute of every convenience necessary for people in that helpless condition.

"Clysters were administered by a mate who crept on all fours under the hammocks, and forcing up his head between two kept them asunder with one shoulder till he had done his duty. Roderick Random tried to follow his example, with consequences of a Zolaesque character which need not be described. He was besides, fixed as it were, in a pillory between two hammocks, and had to be rescued when he was on the verge of strangulation. He had to go close-shaved by way of preserving himself from the parasites which infested the sick berth.

"We get a picture of the cockpit during an action where the surgeon hid himself, and was only induced to get up by threats that a complaint would be made to the Admiral. Fortifying himself with rum, he went to work, and arms and legs were hewn off without mercy. He could not, however, be got to go up on deck to dress a wound received by the captain.

"Random fell ill with what he calls bilious fever, and owed his life to a grateful sergeant whose nose he had mended after a wound during the fight. This man gave him the use of his own berth in the middle deck, which was well aired. They got a new captain, a dandy who sent for Random to bleed him, but distrusted his skill when he saw him. He said to his valet, who from time to time applied a smelling-bottle to his nose: 'Dost thou think this wretch'—meaning Random—'will do me no injury? May I venture to submit my arm to him?' He then politely asked Random if he had ever blooded anybody but brutes; before the operation could be performed, his own surgeon, in whom he had more confidence, turned up. This picture is painted with the detail of a Dutch artist, and apparently Carlyle thought it a faithful pic-

ture, although to some it may seem not untinged with malice, for Smollett had, no doubt, to endure many indignities more serious than that put upon him by the dandy captain. However this may be, the picture may give a notion of the medical service of the British Navy in the middle of the eighteenth century, and of the way in which the patients—and the medical men—were treated.

Correspondence.

MIXED INFECTION IN TUBERCULOSIS.

29 GLOUCESTER STREET,
BOSTON, AUGUST 5, 1915.

Mr. Editor: May I be allowed to comment on your editorial entitled "Mixed Infection in Tuberculosis," which appeared in the *JOURNAL* of July 22, 1915?

While the entire subject of the rôle played by a superadded mixed infection in tuberculous processes is still one concerning which there is much dispute, I doubt very much whether the majority of investigators would in the slightest degree agree with the opinion expressed in your editorial. The work of Dr. Inman coming from the laboratory of the Brompton Hospital in London, which appeared in the *London Lancet* a year ago, is a detailed, painstaking, and most thorough investigation of this subject. Coming from such authority as this, his conclusions merit serious consideration. Dr. Inman believes, as a result of this investigation, that the part played by mixed infections is a very minor one; and that the great majority of the serious symptoms, temperature, rapid pulse, loss of weight and strength, etc., are caused by the tubercle bacillus and its toxins and not by the pyogenic organisms.

While it is of course true that in practically every case these mixed organisms are present, I do not believe that it has been proved that they play an important part in the symptomatology of the disease. The statement which you make, "There is a positive danger in interfering with such infections (cold abscesses in tubercular conditions) for fear of converting these sterile tubercular abscesses into pyogenic abscesses, with serious effect to the patient," is interesting, but hardly in accordance with what has come to be recognized as the best treatment of the condition.

I would strongly disagree with your statement that "In uncomplicated tubercular infection there is tendency to subnormal temperature, and the afternoon rise of temperature is not a universal feature in pulmonary tuberculosis." While in certain instances this statement is true, in the great majority of instances such is not the case.

The statement that "Absence of leukocytosis is considered good evidence of the absence of cavity in cases where the physical signs seem to point, but uncertainly, to that condition" is an interesting point, but one that would merit further study and investigation before being accepted.

It seems to me that the statements expressed in this editorial are liable to cause a certain amount of harm in that they would tend to lessen our respect for the tubercle bacillus and its powers and to lay more stress on what, personally, I believe to be the comparatively harmless organisms which so often accompany the tubercle bacillus itself.

Very truly yours,

JOHN B. HAWES, 2d, M.D.

SOCIETY NOTICE.

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.—The twenty-fifth annual meeting of the Association will be held at Atlantic City, September 14, 15 and 16, 1915 with headquarters at the Hotel Chalfonte.

All physicians interested in physical therapeutics are invited to attend.

J. WILLARD TRAVELL, M.D., *Secretary*.

APPOINTMENTS.

UNIVERSITY OF LONDON.—Dr. Francis Arthur Bainbridge, of the University of Durham, has been appointed professor of physiology at St. Bartholomew's Hospital Medical School.

RECENT DEATHS.

DR. ARTHUR T. HILLS, who died recently at Nashua, N. H., was born in Hudson, N. H., and had been practising physician in New York for many years.

DR. HORATIO N. SPENCER, a practising physician of St. Louis, died on August 7 in Atlantic City, N. J.

DR. THOMAS ALOYSIUS MALONEY, of Springfield, Mass., a graduate of the New York University Medical College in 1898, died at New Britain, Conn., July 13, 1915, aged 40. He was a Fellow of The Massachusetts Medical Society.

DR. MARC FONTAINE, who died on Aug. 9 at Spencer, Mass., was born at St. Huges, Quebec, in 1849. He was educated at Nicolet College and received his medical degree from Victoria College, Montreal. He practised his profession in Spencer for twenty-five years and since that time has lived in retirement.

DR. MARK E. RODEY, who died of appendicitis on Aug. 12, at Lynn, Mass., was born at Fitchburg, Mass. in 1887. He graduated in 1910 from the Baltimore Medical School and since that time had practised his profession in Lynn. He was not married.

DR. JAMES L. WHEATON, who died on Aug. 12 at Pawtucket, R. I., was born in Seekonk, Mass., on March 14, 1823. He graduated in 1846 from the Harvard Medical School and from the Berkshire Medical School in 1847. Since that time he had practised his profession continuously in Pawtucket. He is survived by two aged daughters, and by a son, also a physician.

Address.

ACUTE TUBERCULAR INFLAMMATION OF THE ILEO-COLIC GLANDS SIMU- LATING APPENDICITIS.*

By HOMER GAGE, A.M., M.D., WORCESTER, MASS.

THE attention of the whole world seems just now to be centered on war, with its horrible story of the destruction of property, homes, and human life.

As disciples of medicine and surgery, our interest lies not in the machinery and engines of destruction, but in the means of relieving the suffering and restoring the health of those who are fortunate enough to be enrolled among the wounded rather than the dead.

I presume your thoughts, like mine, have been focussed upon the field and base hospitals where so many poor fellows are carried, and where there is often so much to do and so little to do it with. But perhaps, like me, you have wondered whether after all, in spite of all the difficulties and deficiencies, there must not be a very real satisfaction in dealing with sound bodies, and in the feeling that wherever success is possible, it is going to be permanent; and in escaping even for a little while from our constant and so often hopeless struggle with tuberculosis and cancer.

It is our perpetual war, and is ever fought against tremendous odds, and under most discouraging conditions, discouraging, because the favorable results, at any rate the complete vic-

tories, still seem so far beyond our control and so few.

In some cases we fail, because the infection is in localities that are beyond our reach; in others, because it is so general that local intervention is of little use; in others, our attempts at interference seem to stir up a general infection or cause a transfer of the infection to new fields, most often to the meninges; in still others, our best efforts involve permanent deformity or disability; while in most of them it affords but a temporary and all too feeble check. And yet we must fight on, ever seeking and hoping for more knowledge, better weapons, and new methods.

I have been led to speak to you tonight about one phase of this great surgical warfare against tuberculosis, not because I can offer you any better weapons or new methods, nor have I any new knowledge, but because it seems to me that the subject has not yet received the recognition that its importance warrants. I refer to the tubercular infection of the mesenteric glands in the ileo-cecal angle.

The subject is hardly referred to in our surgical text-books, and has received scant attention in the great surgical systems; but it has occurred often enough in my own experience, to make me feel that it must be more common than we have been led to believe.

It is, moreover, of especial interest, because it so often and so closely simulates appendicitis, and because it seems to offer more than a reasonable chance for permanent cure—the results being distinctly more favorable than in the tuber-

* Read before the Springfield Academy of Medicine, Dec., 1914.

cular glands of the neck, which in some respects they closely resemble.

We have of course been very familiar for a long time with the manifestations of tuberculosis in the abdomen, as a general tubercular peritonitis, or as a general infection of the lymphatics in *tubercles mesenterica*, in the forms of intestinal ulceration, and in the genito-urinary tracts of both sexes; but the relation of these different manifestations to each other, their beginnings and their relation to tuberculosis of the throat and air passages, has been but little understood.

Its discovery as a local process confined to the ileo-cecal glands has not by any means cleared up these difficult and important problems, but it has given us a new viewpoint. It seems not unreasonable to infer that tubercular infection through the intestinal walls, and especially through the wall of the cecum, may be a pretty constant menace; that the natural resistance of the individual may permit it to pass through the whole intestinal tract without inflicting any damage; that with other individuals this resistance may not be strong enough to prevent the invasion, until the lymphatics have become involved and their assistance called into play; in still others, the resistance may be so low that the lymphatics are unable to take care of it, and a general peritonitis or general *tubercles* is the result. These are, of course, mere hypotheses, but they suggest new lines of thought, and new channels for pathological research.

What knowledge we possess of these conditions has been derived chiefly from autopsies and from operations for the relief of tubercular peritonitis,—in other words, we had looked at these conditions only in their later and more advanced stages.

It was only after the right iliac region had become nearly, if not quite, the most operated on part of the human body, that we began to find an infection of the glands in the ileo-cecal angle without demonstrable evidence of tuberculosis anywhere else.

In cases of acute appendicitis we do occasionally find a moderate enlargement of these glands, although it is relatively much more infrequent than it would seem reasonable to expect. Such glands are usually not larger than a small bean, and on section, show simply ordinary inflammatory changes. These are not to be confounded with the tuberculously infected glands about which we are concerned, and which are, as we shall see, often found without any apparent lesion in cecum or appendix.

One of the very earliest cases in which an acute tubercular infection of the ileo-cecal glands was found and the glands removed, was reported by the late Dr. Maurice Richardson before the American Surgical Association in 1900, although the operation had been done five years earlier.

In an operation upon a boy five years of age, undertaken for a supposed acute appendicitis, he

had found "a healthy cecum, and an unaffected appendix, but in the mesentery of the ileo-cecal coil were numerous enlarged glands, varying in size from that of an English walnut, to that of a large pea," two of them had a cheesy content, and all were pronounced tubercular by Dr. Mallory.

In commenting upon this case Dr. Richardson said "cases of this kind must be extremely rare. Not that tuberculosis of the abdominal viscera is rare, for taken as a whole, it is a common disease. Limited, however, to a single small area of the peritoneum, or of the peritoneum covered viscera, it is unusual; limited to an area that permits complete extirpation, it is more unusual still."

At the same meeting of the American Surgical Association, Dr. J. W. Elliott also presented a paper on the "Successful Removal of Acutely Inflamed Tubercular Mesenteric Glands," and reported a case operated upon in 1899, very similar to that of Dr. Richardson.

A year later, in 1901, Dr. Richardson read a second paper, this time before the New York State Medical Society, on "Acute Tuberculosis of the Mesenteric Lymph Glands," but had no more cases to report,—he did say, however, "That unless I am much mistaken, emphasis laid upon this subject by full discussion, with renewed experience, will show that it is not so unusual a disease as has been supposed."

At about the same time Gerard Marchant had called attention to the fact that a peri-cecal tuberculous adenitis could give rise to symptoms of acute appendicitis; and he maintained that the tubercular infection reached these glands through the appendix, even though it, the appendix, presented no microscopic or macroscopic evidence of the infection in itself, a view which is still widely held, especially by the French surgeons.

These are, so far as I can discover, the earliest papers to call attention to an acute tubercular adenitis, limited to the ileo-cecal mesentery, and closely resembling in its clinical aspects, a chronic appendicitis.

Since then, many more cases have been reported, and although they have not even yet attracted very general attention, they are enough to establish beyond question the soundness of Dr. Richardson's prediction that "it would be found not so unusual a disease as has been supposed."

In a paper read before the International Congress for Tuberculosis in 1908, Eisendrath gave synopses of seven cases reported by French surgeons, to which he added two from his own hospital records, in all of which tubercular ileo-cecal nodes were found.

In a discussion of this subject before the New Hampshire Medical Club in 1913, Dr. David W. Parker reported that he had been able to collect the reports of 39 cases, chiefly English and German, to which were added two more that had occurred in his own experience,—and on the

same occasion Dr. Lund of Boston referred to "about a dozen cases of his own, of tuberculosis of the mesenteric gland, with or without a chronic appendicitis."

To these I am able to add from my own records 11 cases of acute and one of chronic tubercular adenitis, limited to the ileo-cecal angle. From the relative frequency with which these cases have been observed in my own limited experience I cannot help feeling that they are much more common than the meagre journal reports and the scant references to them in surgical literature would seem to indicate.

Perhaps they have been so common in the larger clinics, that it seemed hardly worth while to report them; and I should have hesitated to bring so small a matter to your attention to-night, if it were not that the subject opens up some interesting points in the study of infections, and that some of the clinical features seem to me not wholly inconsequential.

Let me briefly restate the exact conditions and its limitations to which I wish to call your attention. It is not the existence of general tuberculosis of the mesenteric lymph glands, but of an acute local infection involving only the glands which drain the ileo-cecal region, and I am not referring to the acute hyperplasia of the ileo-cecal glands occasionally met with in acute inflammations of the appendix and cecum. The condition is that of a primary acute tuberculosis limited to this region.

What is the source of this infection, and why is it found so much more often here, than in any other particular part of the mesentery? In attempting to answer these questions our attention is obviously attracted at once to the structures which are drained by these glands, viz.: to the cecum and appendix.

Corner has pointed out the relative stasis of intestinal contents in the cecum, with the consequent multiplication of micro-organisms here, as perhaps the underlying factor, just as it is probably one of the important factors in the causation of appendicitis.

Tuberculosis of the cecum itself is by no means as rare as was formerly supposed. I have myself removed the cecum twice for tubercular stricture causing chronic intestinal obstruction.

It is of course possible that in the gland infections, there has been a primary lesion in the mucous membrane of the cecum or appendix which has healed spontaneously, or heals after the removal of the glands; but such a supposition is not necessary, because it seems pretty clear that tubercle bacilli can, as Jordan and Corner say, pass through the intact mucous membrane and give rise to gland tuberculosis in animals, without leaving any trace of their migration in the intestinal wall.

This has been disputed by Takeya and Dold of the University of Tübingen, but is accepted by Thiemann, and was affirmed by Dobroklousky as long ago as 1890.

It is moreover in harmony with the clinical

evidence in these cases submitted by a large number of independent observers, which would indicate that in the great majority of them, no demonstrable lesions could be found at the time of operation, and no persistent through-unobserved lesion was indicated by the subsequent history.

Although the glands of which we have been speaking are not so prone to form large infiltrating abscesses as are the acute tubercular glands of the neck, the analogy is nevertheless quite suggestive, especially in some of its clinical aspects; and is further supported by the numerous lymphoid follicles which are contained in the mucosa of the appendix, and which are very similar to the lymphoid tissue in the tonsils.

Numerous instances of what have seemed to be primary tubercular lesions of the appendiceal mucosa have been observed, and there would appear to be no reason why the bacilli should not pass through the uninjured lymphoid follicles of the appendix, just as they are believed to do through the follicles of the tonsils; and to my mind this is the most rational mode of explaining the infection of the ileo-cecal glands, and as has already been pointed out, seems to be the opinion of the French surgeons.

Another interesting question in this connection is the relative frequency of the human and the bovine tubercle bacilli found in infection of the mesenteric glands, and although I am aware of no case of the acute limited forms which we have been considering, in which the differentiation has been worked out, there is an interesting study of 71 cases of mesenteric gland infection in general, by Hess, in which the type of the infecting organism has been isolated and studied.

In 62% he found an infection with the bovine type of bacillus, and goes on to say, "that this type cannot, then, be disregarded, and in connection with the percentage of bovine infection, which has been demonstrated in other organs, these figures emphasize the fact that mesenteric glands form the chief portal of entry for the bovine bacillus, with the tonsils alone to share the distinction."

Had he said that the lymphoid follicles of the intestine formed the portal of entry, I think he would have been more nearly correct.

However the distinction is probably of little importance, as Hess himself reports three cases, two in children, and one in a young adult, in all of which he found the human type; and Theobald Smith, in an article on "A Study of the Tubercle Bacilli Isolated from Three Cases of Tubercular Mesenteric Lymph Glands," says that "The bacilli isolated from these three cases of presumable food infection, do not correspond to the bovine type of bacilli in any one particular."

It may be safely inferred therefore, that both forms are present in these infections, and that milk, cream and butter are not more important factors in the causation of tubercular lymph

nodes, than many others about which we hear much less in the public prints, and before legislative committees.

In reviewing the clinical history of these cases, one finds that the only attempt to make any real classification, is that of Corner, who in his second paper, published in 1908, makes a distinction between the tubercular mesenteric glands found in adults, which he says are most frequent in the ileo-cecal region, rarely form a palpable tumor, and are frequently associated with the appendix, and those found in children, which may be anywhere in the mesentery of the small intestine, usually in its lower part, are due to infection from the small intestine, and usually form a movable palpable tumor under the left rectus.

These conclusions are, however, not confirmed by a study of the cases reported by Thiemann, Richardson, Parker, and the French surgeons, nor by my own.

Four of my cases ranged from seven years to twelve, and seven of them from 16 to 25. In none of them was there a palpable tumor, and in all but one the glands were confined to the ileo-cecal region; and in that one, they were chiefly in the same location, though a few small glands were palpable in other parts of the mesentery.

Neither the findings nor the clinical history differed in any material respect between the younger and the older group. All of the cases happened to be in females. The condition, however, is certainly not confined to one sex, and I am not in a position to say that it is distinctly more common in one than in the other. My own experience would lead me to suspect that it was.

The predominant feature in them all, as well as in most of the cases elsewhere reported, has been an attack of pain and tenderness, localized in the right iliac region, of recent origin, accompanied by a slight rise of temperature, and without demonstrable tumor; in only one of my cases was a small tumor believed to be present. Nausea was present in almost all, but vomiting occurred only in four.

In one case there was a history of two previous attacks of appendicitis,—one six months, and one two years before, another had had her first attack of right iliac pain and vomiting eight months before, had been in bed for two days, and had been unable to stand erect for several days afterwards; she had had six similar attacks before operation. She had two glands in the ileo-cecal angle, each of which contained a large amount of caseous material, on the smears of which tubercle bacilli were easily demonstrated.

The appendix presented nothing remarkable, either upon gross or upon microscopical examination. In these, as in all the rest, the clinical history seemed to point unmistakably to an appendicitis of moderate severity.

One case was especially interesting, because the appendix had been previously removed for the relief of the same symptoms. She had had more or less pain in the right side of the abdomen ever since the operation,—for three days

before entrance to the hospital the pain had been very severe, with nausea but no vomiting; three enlarged glands were found in the ileo-cecal region as big as English walnuts, one was ruptured in the process of removal, and contained a thick cheesy material—culture from which showed no growth. During her convalescence she still complained at times of the old pain, but I am sorry to say that I have been unable to follow her subsequent history.

I have often wondered whether I overlooked some other infected glands, or whether the gland which I ruptured may have infected the peritoneum. Either supposition is of course quite possible, although at the time of her discharge, one month after operation, she seemed to be much improved.

None of the cases presented any evidence in personal or family history suggesting tuberculosis, although in two or three, subsequent investigations revealed the presence of tuberculosis in collateral branches.

It will be readily appreciated that an accurate differential diagnosis in these cases is attended with the greatest difficulty. I have never yet myself been able to make the correct diagnosis before opening the abdomen,—every one of my own operations was undertaken with the expectation of finding an inflamed appendix and I was as much surprised at my twelfth experience, as I was at my first.

I have, moreover, sometimes been led by an atypical history, or by the appearance of the patient, to suspect a glandular tuberculosis, only to find a simple catarrhal or obstructive appendicitis.

It is perfectly possible, I suppose, that personal or family history, or the physical examination may occasionally point clearly to an acute tubercular infection of these glands, but I have never been fortunate enough to meet with such a case, or else I have been too dull to recognize it.

Fortunately, the indications for operative interference are not dependent on an accurate diagnosis. The symptoms in my series were all those of an acute inflammatory process in the right iliac region, so directly suggestive of an acute appendicitis,—and I think no surgeon of experience could have questioned the propriety of operation, and operation without delay.

In all of the other cases which I have been able to study from the reported records, the same positive indication for operation was present, and the appendix seems always to have been suspected as the cause of the outbreak.

In most of them the appendix was removed as well as the glands. It had been previously removed in one of mine, and was taken out in all but one of the others. Why I did not take it out in this one, I cannot now recall, and my record does not state. My present opinion is that it should always be excised.

I have never been able to demonstrate the existence of any tubercular infection or ulceration of the appendix in these cases, although all of

them showed more or less chronic inflammatory or obstructive changes.

The cecum was not opened in any of them, but neither inspection nor palpation suggested anything abnormal. I think that the infection of the glands was without any primary demonstrable lesion in the wall of the cecum or appendix. I believe, however, that the appendix will almost always, if not always, show signs of inflammation or obstruction, and should always be removed.

The technic of the operation is, therefore, that of simple appendectomy, plus the dissection of the infected glands. This should, if possible, be accomplished without rupture of the glands, so that primary union may be obtained. Care must be taken not to interfere any more than is absolutely necessary with the blood vessels of the mesentery, so that the viability of the intestine should not be impaired, and all hemorrhage must be securely stopped.

Rupture of a gland with the escape of cheesy contents, so that there is any material contamination of the surrounding peritoneum, raises the question of the desirability of drainage. Of course, when the escaping contents are purulent, one should always drain, and in the border line cases, the old surgical maxim, "when in doubt, drain," seems to me, still to hold good.

I have not yet met with any cases of mixed infection, though there would seem to be no reason why it should not occur. The laboratory report has been, "no growth from the culture."

It is by no means always possible to obtain the tubercle bacilli from the gland tissue, or on the smear taken from the gland contents. We have been able to demonstrate the bacilli in four of these cases, and have identified the others by finding typical tubercle and giant cell formations.

In spite of the fear with which the announcement of a tubercular infection always inspires us, I think we can very confidently look forward, in the type of case under consideration, to a favorable result.

One can readily understand the disappointment and anxiety which Dr. Richardson tells us was occasioned by the discovery of tubercular glands in his first case in 1895, before the existence of localized glandular infection had been recognized, but his patient is now a strong vigorous young man of 25, and although a very few instances of subsequent generalized tuberculosis have been reported, almost all of them have been free from subsequent manifestations.

Some of my own cases I have been able to follow up to the present time, and to know that they have remained perfectly well. Only one of the others, so long as I was able to follow them, had developed any evidence of tubercular taint, so that I feel that we may safely regard the prognosis as favorable.

All of my cases recovered from the operation, although convalescence was complicated in one by pneumonia, and in another by phlebitis of the left leg.

What would happen if these glands were allowed to remain, raises an interesting question which it is not easy to solve. In the case reported by Parker, adhesions between an inflamed caseous mesenteric lymph gland, the size of a walnut, and the adjacent lower part of the ileum had caused a sharp kink in the bowel, with symptoms of obstruction, and had so infected the bowel as to lead to its rupture during the process of separation.

In other reported cases, considerable abscess cavities have been found. On the other hand Treves says, that he has seen the glands diminish after simple exploration, and the presence of small calcitrated calcareous glands sometimes showing, as described by Corner, in an x-ray plate, like a ureteral calculus, would seem to indicate, that, in some cases at least, there is a definite attempt at spontaneous resolution or cure.

This, however, should not deter us from surgical interference, because our interference is undertaken only when symptoms indicating an acute inflammatory process in the right iliac region are present, and the condition once disclosed by the incision, there can be no question as to the desirability of removing the infected glands.

I have tried thus briefly, and I am afraid very imperfectly, to call your attention to a form of tubercular infection of the mesenteric lymph glands, which is to be distinguished from the ordinary form of *tabes mesenterica*, by being limited to the group of glands situated in the ileocecal angle, and characterized by an acute inflammatory reaction, closely resembling the milder forms of appendicitis.

It is certainly much more common than a review of surgical literature would indicate, and a knowledge of its existence, its proper treatment, and its prognosis is, I think, of importance to every one who is operating in the region of the appendix.

LYMPHOCYTOSIS IN CANCER.—Through the Washington Academy of Science, Drs. John B. Murphy and John J. Morton, of the Rockefeller Institute for Medical Research, announce their belief, based upon experimental observation, that lymphocytosis is associated with increased immunity to cancer. It is suggested, but still remains to be proved, that injection with an extract of lymphoid tissue may increase this immunity.

Discussion.

I.

THE USE OF DIGITALIS IN THE VARIOUS FORMS OF CARDIAC ARRHYTHMIA.

BY HENRY A. CHRISTIAN, M.D., BOSTON.

IN recent years new methods have been available for studying cardiac action in man; methods which make possible an accurate analysis of the contraction wave, as it sweeps over auricle and ventricle, with a better understanding of disturbances in heart rate and rhythm. The polygraph and the string galvanometer or electrocardiograph are the instruments which have been of greatest service in this study. With them the action of digitalis on the human heart can be investigated with the thoroughness that is used in the pharmacological laboratory for animal experimentation, with the very great advantage that it is the human heart disturbed by natural disease that is being studied, not the normal heart of an animal or an animal's heart in which man's acquired disease is but crudely imitated.

It is my task this afternoon to place before you some of the results of this work. I will attempt to give an interpretation and an application to clinical practice of studies which have been conducted in many clinics rather than to report any new studies of my own. However, instead of analyzing the literature on the subject or quoting the opinion of others I will give deductions from this work as we have attempted to apply it to patients observed in the clinic of the Peter Bent Brigham Hospital.

Now if the application of the polygraph and electrocardiograph to the study of cardiac disorders is to be of any real usefulness to the general practitioner of medicine, the knowledge gained from such studies must be translatable into the terms of general practice, that is, brought into the range of such observation as is possible with finger, eye and stethoscope. I believe that by the use of very complicated and expensive apparatus we have acquired so much better knowledge of cardiac arrhythmias that we are in a position by very simple means to recognize accurately the common arrhythmias, and understanding better their mechanism we can

apply in their treatment our therapeutic measures with far greater success.

Irregularity in heart action may arise in several ways. Normally the contraction impulse begins at a point in the region where the superior vena cava joins the right auricle and spreads over the auricle as a contraction wave. The contraction of the auricle originates an impulse which travels from auricle to ventricle along the conduction system or His bundle, and arriving at the ventricle starts almost simultaneously in many parts of the ventricles a contraction of ventricular musculature which drives out into the peripheral vascular system a certain amount of blood. Irregularity in heart action will result from disturbances at the point of origin of the impulse, in the auricle, in the conduction system or in the ventricle. For our purposes we

FIG. 1.—Patient with auricular fibrillation. Dots joined by solid line indicate radial pulse rate. Circles joined by solid line indicate apex rate. need discuss only those arrhythmias which frequently are associated with or are the cause of cardiac decompensation. As with cardiac murmurs so with cardiac arrhythmias, it is the evidence of cardiac decompensation that should indicate the need for therapeutics, not the finding of an irregular pulse.

One of the most frequent arrhythmias in this sense of causing cardiac decompensation is auricular fibrillation, a condition in which the auricle instead of contracting regularly and rhythmically, at a rate of 70 to 90 per minute, is in a condition of very rapid fibrillary twitching with no functional contraction in the sense of squeezing its contents into the ventricle during the period of ventricular diastole. There being no orderly sequence of contractions in the auricles, these fibrillary twitchings are continually starting impulses along the conduction system of varying intensity, to only some of which can the

ventricular musculature respond by contraction. The result is an extreme irregularity in the rate and force of the heart beat. The diagnosis can be made readily in most cases by feeling the pulse and finding an irregularity in rate and force which is without any suggestion of a dominant rhythm. If the patient shows signs of cardiac decompensation the stethoscope over the heart apex will reveal the same type of tumultuous irregularity in rhythm, and with the finger on the radial pulse there is a striking difference between apex rate and radial pulse because some of the weaker ventricular contractions fail to give an impulse to the blood stream that reaches the radial artery as a pulse wave. Finding a marked irregularity in pulse rate and a striking discrepancy between apex rate and radial pulse, the diagnosis of auricular fibrillation is justified. With auricular fibrillation digitalis almost invariably produces a striking effect, as shown by

Fig. 2.—Patient with auricular fibrillation. Dots joined by solid line indicate radial pulse rate. Circles joined by solid line indicate apex rate. Dots joined by broken line indicate urine output in c.c. Circles joined by broken line indicate fluid intake in c.c. Arrows over A² indicate days on which the patient received three doses of 0.1 gm. each of powdered digitalis leaves. Arrows over A³ indicate days on which the patient received two doses of 0.05 gm. each of powdered digitalis leaves.

Fig. 1 and Fig. 2, unless the myocardium is damaged so extensively that no longer can it respond to the digitalis.

The effect of digitalis is to slow the pulse rate (Fig. 1) and to increase the work of the heart, as shown by decrease in the signs of cardiac decompensation (edema, subcutaneous and pulmonary, ascites, cough, bronchitis, dyspnea, etc.). Sometimes there is a diuresis (Fig. 1); sometimes not (Fig. 2). A very important evidence of the beneficial action of digitalis is the decrease in the pulse deficit, i.e. in the difference between apex beat and radial pulse (Figs. 1 and 2). In using digitalis it is particularly important to keep this effect in mind, for if one counts the radial pulse alone there may be no particular change in pulse rate, though the number of cardiac contractions has been materially decreased (Fig. 2). In fact in this form of cardiac arrhythmia the counting of the radial pulse may be very misleading, it being within normal limits when actually the heart is beating very rapidly (Fig. 2). To count the heart beats with the stethoscope is the all important thing, not the counting of the radial pulse.

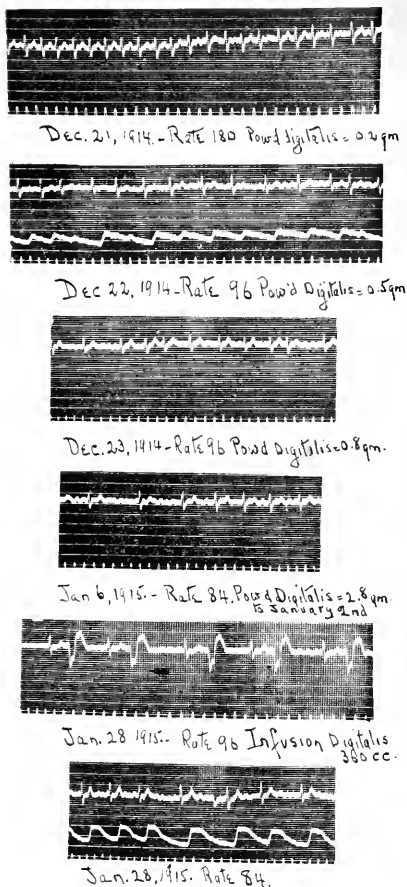

FIG. 3.—Electrocardiograms from patient with auricular fibrillation. Upper four curves show progressive effect of digitalis given in one period. The fifth curve shows bigeminy produced by digitalis given in another period. The sixth curve taken immediately after the fifth shows temporary character of bigeminy in this patient.

How does digitalis act in these cases of auricular fibrillation to improve the heart action? It is mainly an effect through the conduction system; digitalis impedes conduction in the His bundle, and the result is that fewer auricular contractions send through impulses to originate ventricular contractions, and so the ventricle beats more slowly. Beating more slowly, there is more time for the ventricle to fill and more time for the muscle to recover from fatigue, so the systolic output is increased. Probably also digitalis exerts an action on the myocardium, causing the contraction to be more forcible, and by its action it improves coronary circulation. Digitalis in these cases produces no effect on auricular contraction:—fibrillation continues as be-

fore. These effects are shown by the electrocardiograms (Fig. 3). If digitalis is pushed too far, nausea usually develops as a signal for its omission. In other cases a characteristic toxic effect appears,—the pulse becomes bigeminal. Electrocardiograms show (next to last curve in Fig. 3) that this bigeminy is produced by a ventricular extra systole or ectopic beat, following closely after the regular ventricular contraction whose impulse has originated in the auricle. This condition is easily recognized with the stethoscope over the heart or by the palpating finger at the wrist. Whenever a coupling of the beats is detected with pauses of varying length between the couples and a pretty constant interval between the two beats of the couples, one can feel pretty sure of the existence of this toxic effect of digitalis in a case of auricular fibrillation. The condition may persist for some time or the rhythm may return quickly to its original form (see last curve Fig. 3), depending upon the severity of the toxic effect of the digitalis. The occurrence of this phenomenon is a sign, of course, for the omission of digitalis.

In some cases with auricular fibrillation in which edema is marked a much better diuresis is obtained by combining with the digitalis a diuretic drug, such as theocin (Fig. 4).

In another form of arrhythmia, namely, auricular flutter, digitalis usually produces a very striking effect. By auricular flutter is meant a condition in which the auricles are beating regularly and very rapidly, over 200 per minute (Fig. 5), too rapidly for the ventricle to respond to each auricular impulse. As the ventricle lags behind the pulse becomes slightly irregular, with a tendency for the irregularity to come in groups which repeat themselves. However, this condition usually is difficult of diagnosis except with the electrocardiograph. Digitalis in these cases either throws the auricle into fibrillation and when digitalis is stopped the normal rhythm is restored, or the heart slows down directly into a normal rhythm with great improvement in the patient's condition.

The action of digitalis in flutter is a twofold one. There is an action on the auricle which disturbs the ectopic focus of impulse formation, which is responsible for the very rapid auricular beat, either in inhibiting it and allowing the normal pace maker to regain control, or by generally disturbing the auricle so as to produce fibrillation, from which normal rhythm is restored. In addition there is an action on the conduction system and ventricular muscle such as occurs in auricular fibrillation cases.

In these two forms of arrhythmia the effect of digitalis is more constant and more striking than in any of the other common types of arrhythmia.

In pulsus alternans frequently digitalis produces good results. In true pulsus alternans the pulse is regular in rate but every other beat is weaker than its predecessor (Fig. 6). In such a case the pulse rate may be definitely slowed by

digitalis (Fig. 7) with much improvement in the patient's condition. It is to be remembered, however, that a pulsus alternans is a sign of a very much impaired myocardium, and when the myocardium is greatly impaired the likelihood of functional improvement from digitalis is much decreased. To push digitalis in such a case may do much damage. Here it is particularly difficult to judge how far to carry digitalis therapy if no evident effect is produced. It would seem that in many of these cases the margin between no therapeutic effect and a serious toxic effect is a very narrow one. The same thing holds true for the rapid, regular, though decompensated heart.

In the rapid, regular, decompensated heart digitalis, when it acts, appears to have a three-fold effect. It slows the rate by increasing vagus inhibition and by increasing conduction time between auricle and ventricle (Fig. 8), and it strengthens heart action by some direct action on the myocardium and coronary circulation. This type of case often seems definitely resistant to digitalis and the patient may take large amounts before any effect can be detected.

It is always well to remember in such cases to watch the patient carefully, for sometimes the digitalis action, which has been long delayed, develops with great rapidity into marked activity so that the patient, who shortly before has shown no digitalis effect, quickly develops toxic symptoms.

In paroxysmal tachycardia there is very little evidence that digitalis produces any good effect. In sinus arrhythmia and in compensated hearts with ectopic beats or extra systoles digitalis is not indicated. Sinus arrhythmia is easily recognized by palpating finger or stethoscope as a rhythmic variation in interval between successive beats, frequently a rhythmical variation synchronous with respiration. Extra systoles or ectopic beats are familiar to you as dropped beats. Two beats come rather close together and

FIG. 4.—Patient with auricular fibrillation. Dots joined by solid line indicate radial pulse rate. Circles joined by solid line indicate apex rate. Arrows over A¹ indicate days on which the patient received three doses of 0.1 gm. each of powdered digitalis leaves. Arrows over A² indicate days on which the patient received two doses of 0.05 gm. each of powdered digitalis leaves. Arrows over A³ indicate days on which the patient received three doses of 0.1 gm. each of infusion of digitalis. Arrows under B indicate doses of 0.5 gm. each of theocin.

the second of these is followed by a lengthened pause. The extra systoles usually come at no fixed rate. Both these types of arrhythmia occur often in hearts with no other evidence of disturbed function, and their presence calls for no digitalis therapy. In decompensated hearts with a moderate number of extra systoles digitalis is indicated and acts much as it does in the decompensated heart with regular rhythm. When extra systoles are so numerous that cardiac decompensation appears to be largely a result of the arrhythmia, much caution is required in using digitalis because there is some evidence that digitalis at times increases the number of extra systoles and makes matters worse. However this question of the exact relation of digitalis to extra systoles is one still under discussion. In most cases extra systoles are more an

incident in, rather than a cause of, cardiac decompensation, and their presence can be neglected in considering the probable efficiency of digitalis therapy.

In cases of heart block not of digitalis origin, digitalis should be tried if the patient is decompensated.

Results are sometimes very good; at other times it would seem that the patient is made worse. Trial must be made to determine this. So digitalis should be applied, but caution in its use in heart block is necessary.

It is rather beyond the province of my part in this symposium to discuss the various forms of digitalis. However, it seems to me that the all-important things are to see that the form of digitalis used is an active preparation and to use it in sufficient dosage to get effects. In my own judgment various digitalis preparations are interchangeable in ratio of their potency, and consequently it makes no difference what form you use provided you use it in the proper kind of a case in sufficient dosage. Any form used by mouth will require more than 24 hours to produce an effect. A form of digitalis preparation suitable for intravenous use so introduced into the body will begin to produce an effect in a few hours, often within one hour, and this form is indicated where prompt actions are required. Subcutaneous use gives an effect less rapid and less certain than intravenous use. Furthermore, most of the preparations which are potent are apt to be irritating when introduced subcutaneously. It seems to me that when quick action is required or the patient is vomiting and cannot retain the drug, intravenous use is preferable to subcutaneous. In the hospital I have the apothecary purchase good powdered digitalis leaves, whose potency I find out by using them in patients such as cases of auricular fibrillation in which digitalis ordinarily works well. If I get good effects I know that lot of digitalis is potent. In the form of powdered leaves or freshly made infusion I find I can treat effectively the large proportion of cases with cardiac decompensation. For simplicity I use only these two forms of digitalis for mouth dosage. Occasionally a case requires a prompt action or is vomiting. In such a case I use strophanthin intravenously, with due regard to the necessary caution against using strophanthin in a patient who has been taking digitalis by mouth. Very occasionally it seems desirable to use some form of digitalis subcutaneously. For this I choose liquid digipuratum. I can see no advantage in multiplying the number of preparations of the digitalis group beyond this until new knowledge has come to throw light upon cardiac therapy which will enable us to select active components of the digitalis bodies to fit the needs of certain types of cases. As to dosage, relatively large doses should be used in periods of decompensation. With compensation restored very small doses continued over long periods certainly seem to be of great help in maintaining compensation. Much clinical experience supports this, and the recent electrocardiographic studies of Cohn and others show that the digitalis effect on the heart muscle is long continued after dosage has ended, and presumably with a continuation of small doses this effect is maintained.

FIG. 7.—Patient with pulsus alternans. Dots joined by solid line indicate radial pulse rate. Dots joined by broken line indicate urine output in c.c. Circles joined by broken line indicate fluid intake in c.c. Arrow over A¹ indicates intramuscular dose of 1 c.c. of digipuratum. Arrows over A² indicate days on which the patient received three doses of 0.1 gm. each of powdered digitalis leaves.

If you use a single digitalis preparation which you know to be active by mouth and use it in a dosage which you have learned to be effective it seems to me you have solved the problem for all cases except those requiring intravenous or subcutaneous digitalis therapy, and these latter are few. If, in addition, you have chosen a potent preparation for these occasional requirements, it seems to me you are in a position to toss into the waste basket all samples and literature on improved preparations of digitalis. You can reduce it to two forms, one for mouth use and one for intravenous use, and get as good results as any of your colleagues if you select the suitable

FIG. 8.—Electrocardiograms from patient with regular rhythm showing effect of digitalis on conduction time between auricle and ventricle. The second curve shows a partial block in conduction.

type of case in which to push your digitalis therapy. One good preparation for mouth use with common sense and a knowledge of cardiac pathology and physiology will suffice for the successful treatment of most of your cardiac cases. I would suggest that you have a reliable druggist keep in stock for you in powdered form a good digitalis leaf whose efficiency you know from using it on your own patients. From this leaf have him fill your prescriptions of pills of powdered leaf or fresh infusion. Equally well might you use tincture, but its preparation requires considerable time. Insist that your patients have their prescriptions filled by this one druggist. Doing this I believe you will improve greatly the results you obtain from digitalis, and digitalis properly used in cardiac disease is a most effective remedy, an all-sufficient answer to those who have no faith in therapeutic measures.

II.

THE RELATIONSHIP OF THE ABNORMAL HEART BEAT TO PROGNOSIS.

BY PAUL DUDLEY WHITE, M.D., BOSTON.

THE heart beats abnormally when there is any abnormality of its rhythm, conduction, or contracting power. Sometimes all three and frequently two of these three cardiac functions are defective. During the past few years much attention has been directed to the determination and interpretation of signs and symptoms of abnormalities of the heart beat. The value of various phenomena in estimating cardiac damage and in forecasting the patient's future is being studied and this study should yield steadily more and more guides for our assistance. The field is still relatively recent, but enough years have now been spent by such men as James Mackenzie and Wenckebach to render profitable a summary of the subject as we know it at the present time. We may consider the abnormal heart beat most practicably by taking up in detail disorders of rhythm, conduction, and contraction.

1. DISTURBED RHYTHM.

The most common disorder of the rhythm of the heart is the *premature beat* (the extrasystole of old). It may arise in auricle, ventricle or junctional tissues. (Fig. 1.) Mackenzie² claims that the premature beat adds practically nothing to his opinion of a case whether favorable or unfavorable. In a young healthy person a premature beat should not be a source of concern, even though it does mean that there is an abnormal irritability somewhere in the heart. People have lived comfortably through lives of hard work till old age with the constant companionship of premature beats for fifty years or more. Sometimes this irregularity can be traced to tobacco or to exhaustion and in these cases it will stop

when the causes are stopped. The finding of ventricular premature beats in old people who are growing short of breath or in younger people with high blood pressure or syphilitic hearts may be important, for here one may discover the significant *pulsus alternans* which not infrequently follows the premature beat in such cases.

The frequent association of the much less common type of premature beat—that arising in the auricle (Fig. 1b)—with auricular fibrillation and paroxysmal auricular tachycardia (including flutter of the auricles) causes one to regard this type as more important prognostically than the ventricular premature beat as a possible forerunner of more serious conditions.

Finally, there is a third and uncommon type of premature beat, that which arises in the junctional tissues between auricles and ventricles. This premature beat is unimportant and may be dismissed with the observation that it shows an irritable condition of the node of Tawara or bundle of His and may be classed prognostically with the ventricular premature beat. The differentiation of the types of premature beats is usually possible only by graphic methods.

Paroxysmal tachycardia (Fig. 2) is the next disorder of the cardiac mechanism to be considered, following in direct sequence after premature beats. It consists of a rapid repetition of premature beats, all arising in the same abnormal focus in the heart muscle. It is almost always auricular in origin and sometimes occurs in patients who later show flutter or fibrillation of the auricles. There are people who have paroxysms of tachycardia at intervals for many years and, provided the paroxysms are brief, enjoy good health. Here again, however, the heart muscle is shown to be irritable and to a higher degree than in the case of premature beats. The irritability often expresses itself only under some mental or physical strain. Without other signs of cardiac trouble than the paroxysmal tachycardia the patient may usually be reassured but warned against excesses.

FIG. 1.

A. Ventricular.

B. Auricular. Jugular pulse proves auricular origin of the premature beat.

Time interval = 0.2 sec.

FIG. 2.

Radial pulse tracing showing a brief paroxysm of tachycardia. Preceding the paroxysm appears a ventricular premature beat. Time interval = 0.2 sec.

Closely associated with paroxysmal tachycardia is *auricular flutter*, which is an auricular tachycardia of high degree, almost always with heart block associated with it. The prognosis is less favorable than in the case of simple paroxysmal tachycardia, the evidence pointing as a rule to more serious myocardial damage. In some instances, however, patients showing this condition may live comfortably for years after their return to normal cardiac rhythm. Of seven cases of auricular flutter seen at the Massachusetts General Hospital during the past ten months (August, 1914, to June, 1915) two have died (29%), one had auricular fibrillation when last heard from, and the other four have had recurrences of the flutter. Of the last mentioned four, one has now an atrioventricular rhythm (that is, a pacemaker situated in the junctional tissues between auricle and ventricle), another has frequent ventricular premature beats and alternation of the pulse, a third has so many paroxysms of flutter that she is incapacitated, and the fourth, although in fair health, has shown auricular premature beats between attacks. In distinguishing flutter from paroxysmal tachycardia graphic records are practically essential.

Now we come to the most important disturbance of rhythm—the absolute irregularity of the heart in *auricular fibrillation*. (Fig. 3.) The prognosis in this condition is extremely variable, being dependent on the condition of the ventricular muscle, which must bear the brunt of the irregular passage of the impulse from the auricles, and also dependent on the response of the patient to digitalis therapy. From the moment of discovery of this irregularity until death any length of time, from a few hours to many years, may supervene. In 1881 Potain, by tracings of the radial pulse, found the presence of absolute arrhythmia in a young externe of the Paris hospitals; in 1913, thirty-two years later, Heitz¹ by polygram, found

the fibrillation still existing in this man after an active professional life during which the irregularity had never ceased. Of 86 patients with auricular fibrillation seen at the Massachusetts General Hospital in the past ten months (August, 1914 to June, 1915) 14 (16%) are known to have died. Five are now living comfortably who have suffered in the past from the rather unusual paroxysmal type of fibrillation.

Sometimes a marked arrhythmia is produced through nervous influences acting directly on the pacemaker at the sino-auricular node. This so-called sinus arrhythmia usually is respiratory in origin, but may be due to factors such as increased intracranial pressure and to other causes not well defined. Although at times distinctly abnormal, this disturbance of rhythm as a rule has an extracardiac origin, and therefore should not impress one unfavorably with respect to the condition of the heart. Finally, disorder of the cardiac rhythm may be produced by heart-block, which should be considered under the second heading.

II. DISTURBANCES OF CONDUCTION.

All degrees of *heart-block* may be found from the simple prolongation of the interval between auricular and ventricular contractions, through the stage of dropped beats and 2 and 3 to 1 block, to the rare condition of complete heart-block. (Fig. 4.) Toxic block, usually transient, may be caused by digitalis and allied drugs, acute infection and asphyxia (shown experimentally). This type of block has little value prognostically, except in some cases to evidence a damaged bundle which has been easily depressed by the toxin. If the block is not traceable to toxic cause, but seems to be due entirely to disease or degenerative changes in the bundle, the prognosis must be guarded, for the block in such a case is but an

FIG. 3.

FIG. 4.

Radial pulse tracings showing heart block.

A. Partial block. Early in the tracing there is a "dropped beat." Later every third beat is dropped.

B. Complete heart block. Rate = 42.

Time interval = 0.2 sec.

index of widespread damage in the myocardium. The progressive nature of the destructive process may be followed easily in some cases by the observation of the evolution of the block itself from mild to more extensive grades. The Stokes-Adams syndrome is most frequent in partial heart block, with marked depression of the bundle at intervals. When the block becomes complete in such a case the patient may improve considerably and live comfortably for years. The prognosis of any case of permanent block, especially of the higher grades, should be regarded as grave, although in some instances years may elapse between the discovery of the block and death.

Not only may the main stem of the bundle of His be involved to produce a blocking of the cardiac impulse from the auricles, but also its branches, large and small, may be damaged. At present it is impossible to detect lesions of the smaller twigs of the conduction system in the ventricle, but it is possible by electrocardiograms to recognize gross defects of the two main branches, right and left, which go to right and left ventricles respectively. The left branch is involved much less frequently than the right. At the Massachusetts General Hospital, in the past eight months, of twelve cases of bundle branch defect only one has been of the left branch. The main stem of the bundle of His in such cases may not be damaged sufficiently to cause delay between auricular and ventricular contractions, and the pulse may be perfectly regular at a rate close to 70 per minute. (Fig. 5.) The hidden damage is, however, revealed by the electrocardiogram and is of considerable value prognostically. Any beats in which there is defective conduction in the branches of the bundle of His are called aberrant, thus indicating the abnormal distribution of the cardiac impulse in the ventricles. Reduplications of the heart sounds may accompany these branch lesions, in which one ventricle receives the impulse appreciably before the other. As in the case of lesions of the main stem, so lesions of the branches of

the bundle evidence widespread myocardial damage and are found usually in sclerotic hearts. Two of the twelve patients with branch lesions at the Massachusetts General Hospital have died within eight months of the time when the lesions were discovered; several of the survivors are in poor condition at the present time.

III. DISTURBANCES OF CONTRACTING POWER.

Finally we come to abnormalities of the contracting power of the heart. Weakness in the contraction of the heart muscle is often associated with defects in rhythm and conduction. The coexistence of considerable abnormalities of two or of three of these properties of the heart increases the gravity of the prognosis (for example, heart block or arrhythmia combined with myocardial weakness). Defect in the contracting power of the heart may itself be enhanced by disturbance of the rhythm, as in the rapid irregular action of auricular fibrillation. Help may come on the other hand if the conductivity of the heart is defective—such defect may be artificially produced through the administration of digitalis. In the estimation of myocardial exhaustion the symptoms and general physical signs of the patient taken collectively are of much value and are generally used as the criterion of the cardiac condition: dyspnea on exertion, weak heart sounds, edema of extremities and lungs, and cyanosis. But the history of the frequency of "cardiac breaks" and the way in which the patient reacts or has reacted in the past to rest and digitalis must control one's prognosis.

It is in the doubtful cases showing little else than arrhythmia, palpitation or slight dyspnea on exertion that oftentimes one is most interested in the prognosis. Swan⁴ in a recent investigation, in a series of cases, of several methods which have been proposed as guides in the determination of incompetence of the myocardium in doubtful cases, concludes that two of the methods have more value than the others, namely

Fig. 5.

Graphic records from patient showing defective conduction in the left branch of the bundle of His.

A. The three electrocardiographic leads.

B. Radial and jugular tracings, showing an absolutely regular pulse with slightly prolonged a-c interval.

Time interval = 0.2 sec.

Tigerstedt's efficiency factor, which is found by dividing the systolic pressure multiplied by the pulse rate into the pulse pressure multiplied by the pulse rate, the other method being the determination of the percentage of pulse pressure formed by the second auscultatory phase. He considers as abnormal figures of 40% or more in the former and 30% or less in the latter test. It is very doubtful, however, whether these methods will prove of real worth; in some cases at least they are contradictory and in others far from convincing. Continued study of the blood flow in the determination of the time volume of the heart beat may yield in the future indications of value in the estimation of the efficiency of the heart.

Moritz³ has recently summarized the present status of clinical signs of beginning heart weakness, and concludes that nearly all signs or symptoms taken alone have little value, and that one must study a case from all angles in order to make a fair estimation of the heart's strength. He does not consider the size of the pulse or the blood pressure as reliable signs which can be interpreted at present. He is inclined to lay more stress on venous pressure as evidence of stasis, on the persistence (especially during sleep) of increased pulse rate following exercise, on nocturnal dyspnea, on the gallop rhythm of the heart, and on abnormal sensations in chest and arm. He pays little attention to the character of

the pulse because of its considerable modification by local conditions of the artery. On the other hand there is one condition of the pulse which is an important evidence of exhaustion of the myocardium—that is the variation in force of the pulse beats found either with absolute irregularity in some cases of auricular fibrillation or alternating regularly in some cases with normal rhythm. In the first instance the arrhythmia itself points to an abnormal heart, but in the second the pulse may be perfectly regular or interrupted only occasionally by ventricular premature beats. The alternating character of the force of pulse waves is best seen on radial tracings and gives the condition its name of *pulsus alternans* (Fig. 6). Alternation of the pulse is one of the most important signs which we possess of defective power of contraction of the heart and has been shown by Mackenzie and others to be of very great prognostic significance in cases not showing paroxysmal rapid heart action at the time (in such cases there may be temporary exhaustion from the rapid rate). The alternation may exist in individuals obviously mortally ill but also in cases in which one sometimes would doubt the presence of myocardial weakness. Patients who show *pulsus alternans* usually survive but a few years at the most, the longest case on record being one of Tabora's⁵, living six years after the alternation was first discovered. Of 83 patients with *pulsus alternans*

Fig. 6.
Radial tracings showing alternation of the pulse.
A. Constant *pulsus alternans*.
B. Post-premature beat alternation.
Time interval = 0.2 sec.

and heart-rate below 125 and as a rule below 100 per minute, seen at the Massachusetts General Hospital in the past ten months (August, 1914 to June, 1915) twenty-six are known to have died—that is nearly one-third, which is twice the death rate of cases with auricular fibrillation during the same length of time. Whether we accept the theory of Wenekebach, that alternation of the heart is due to an alternating total hyposystole, or the theory of Gaskell and Hering, that it is due to an alternating partial asystole resulting from the prolongation of the refractory phase of the muscle fibres, at any rate we can feel certain that the *pulsus alternans* is evidence of defect in the contracting power of the heart.

SUMMARY.

Of disturbances of the rhythm of the heart beat, auricular fibrillation (absolute irregularity) and auricular flutter have the gravest prognosis, for not only are these conditions indices of myocardial damage, but they themselves increase the difficulty of the circulation by their rapid driving of the heart. Sometimes, however, many years may elapse before the death of these patients. Of 86 cases of auricular fibrillation seen at the Massachusetts General Hospital 16% are known to have died within ten months of discovery. Premature beats and paroxysmal tachycardia are compatible with a long and active life, but their frequent association with cardiac damage should lead one to be a little cautious in prognosis.

Permanent damage to the atrioventricular bundle of His or its branches is evidence of widespread damage to the myocardium. Hence the prognosis of a patient showing such a condition should be guarded.

Defective contraction of the heart as shown by familiar symptoms and signs, has a prognosis dependent on the number and degree of these symptoms and signs, plus a consideration of similar trouble in the past and of the way in which

the heart responds to rest and digitalis. Of all the individual signs of abnormal contracting power of the heart *pulsus alternans* is one of the most important and consistent. Of 83 cases of alternation of the pulse seen at the Massachusetts General Hospital 31.3% are known to have died within ten months of discovery.

III.

THE TREATMENT OF HEART DISEASE.

By F. C. SHATTUCK, M.D., BOSTON.

THE treatment of heart disease, the subject assigned to me, is no small one. Respecting, therefore, time and place, it will be my effort this afternoon to deal with principles rather than details. Congenital heart disease I shall not discuss.

The treatment of heart disease.

In the first place, we rarely treat heart disease. In rheumatic endo-pericarditis we use the salicylates, though, at least as far as my experience goes, they have no such control here as they have over rheumatic arthritis. If I am right, a possible explanation may lie in the fact that the heart cannot rest as the joints can. Some syphilitic hearts are greatly benefited by potassium iodide. Which these are can be rarely known. We must try. With salvarsan in luetic heart disease I have no experience, my hospital life having closed three years ago. Dr. Sears tells me he has had brilliant results from its use in some cases, notably in aortitis, and in endocarditis of combined luetic and rheumatic origin. I trust we may hear more on this most important point. The discovery of the pale-faced spirochete has greatly enlarged and clarified our knowledge of cardiac syphilis.

The weak heart, which may follow almost any form of acute infection, needs imperatively rest and time; the latter may be abridged by wise medication.

Were I to obey the letter rather than the spirit of the invitation of our distinguished chairman, I should stop here, inasmuch as, except as above stated, we do not treat heart disease, but patients with diseased hearts. Sometimes the patient occupies the foreground, sometimes the heart; but both are always there, interdependent, and the best results are obtained only when the claims of each are duly weighed and welded.

But let us pause for a moment. The first step in making a hare soup is to catch the hare. Before treating a heart as diseased, let us be sure it is such. A disordered heart may be in no way diseased, though a diseased heart may be also disordered, and then offer a very pretty problem as to which of these elements is pre-potent at a given time. Hearts remind me somewhat of boys. A boy may act like the very devil and yet be a good boy—yes, a first-rate boy. Such boys are to be cured by a study and change of their environment; disordered hearts in like manner, by searching out and removing near or remote foci of reflex irritation. I am led to touch on this point by having seen many patients dosed with digitalis, strychnia, etc., apparently solely because the heart was rapid, irregular or intermittent. A number of years ago, an eminent and valued member of our profession consulted me about his heart, which was troubling him, asking whether his was a heart to exercise or to rest. I decided in favor of exercise, and his vigorous condition today shows that my guess was happily right.

Allow me to pause another moment. The heart is a single organ, unlike the lungs and some of the glands total loss of one of which may not be really crippling. Like the lungs, the heart can never have absolute rest, as can the stomach. The healthy heart has an enormous reserve power and a wonderful capacity for adapting itself to changes, extrinsic or intrinsic, especially if such change is gradual in development. Its tolerance of insult is far greater than we realized until recently. Dr. Cushing tells me that after rifle shots through the heart, even the thin-walled auricle, recovery has taken place in the war now in progress. We can determine the condition of the valves with surprising accuracy, but the valves are passive, so to speak. It is the heart muscle which is active and vital, and its condition offers far greater difficulty of diagnosis. That this should be so during life is not to be wondered at, when we see the pathologist often hesitate with the heart in his hand, and fail to get adequate knowledge even with his microscope, as to why the heart gave out.

Let us now assume that we have a diseased heart to deal with. I was brought up to be chary of telling people that they have heart disease,

but I became convinced long ago that, while it is best to be frank as to the indisputable facts, we should be as optimistic as to the outcome as the facts will warrant. We can usually be very sure as to whether or not a heart is diseased in fact. How long a given heart will last is so often a matter of opinion, and therefore liable to great error. The patient should have the benefit of all the doubt. Even if compensation is good and the lesion apparently non-progressive, the patient should so live as to maintain myocardial nutrition. This he is far more likely to do if he knows, and in a broad way understands, the reason for so doing. Nowhere more than in cases of heart disease is the intelligent coöperation of physician and patient essential to the best results. In fully compensated cases direct treatment of the heart is practically never called for.

When compensation is inadequate the treatment of the patient does not lose in importance and may be easier to carry out, inasmuch as he better realizes the need of help—is more ill. But now treatment of the heart itself, direct treatment, is called for in addition.

Of myocardial failure there are all grades in degree and gravity alike. The cause of failure may be a most important factor in aligning treatment. There is thus room for great judgment and acumen. Mere routine, like a "man-hole cover in anger is ten times worse than hell."

The major marks of myocardial failure are edema, pain and shortness of breath. The latter is common to the first two, but may be the leading symptom, especially in cases of mitral disease at or near the margin of compensation. Let us consider edema and pain separately, in the hope of saving time.

The gravity edema of heart disease suggests dilatation of the right ventricle as a whole, and is usually secondary to mitral disease, with which aortic or tricuspid lesion may be combined. It is our aim to promote and restore, as far as may be, myocardial efficiency. There are, broadly speaking, two ways open to us:—

(a) The indirect—reduction of the load of the heart.

(b) The direct—stimulation of the heart power.

Under (a) comes first and foremost rest, to such a degree and for such a time as the individual case may seem to require. It is better to underdo at first, rather than to overdo, as err at times we must; but in non-fatal cases the time is apt to come when a measure of exercise promotes myocardial nutrition.

Moreover, is it not possible that a reason why mitral stenosis is so much more common in women than men is that non-active female life gives a better chance for smouldering inflammation to glue together the edges of the valve curtains? In passing I merely allude here to the obese heart, which we exercise at the same time that we reduce its load by diet and other means.

How blessed may be a narcotic or hypnotic in securing rest! Morphia is *facile princeps*. Massage, active, passive, and resisted movements, skilfully applied, may do vicarious heart work. Watery catharsis does not weaken the dropsical heart patient, and it may be well to explain this to him. I am inclined to think we are not always bold enough in our use of hydragogues. Serous effusions, if marked or obstinate, are to be tapped. Drainage of the legs by Southey's tubes or a modification thereof may be a help. In cases of markedly over-distended right ventricle, and in these cases cyanosis is usually pronounced, venesection up to a pint or more may be the first procedure indicated. The effect is sometimes almost miraculous. A dozen leeches, followed by poulticing their bites, may have a similar effect in relieving the right heart and be a substitute for venesection, if this is for any reason thought to be undesirable. One of the upper quadrants of the abdomen is a convenient place for leeching. Bleeding may pave the way for direct cardiac treatment, digitalis, which was of no use before relief of the right ventricle, manifesting its power thereafter.

In all cases of heart dropsy we watch closely the amount of urine and are apt to try to increase it. The dropsy is not only a measure of cardiac efficiency, but also a hindrance thereto.

The diuretic action of calomel seems to be due, at least in part, to its effect on the renal cells. I avoid its use for this purpose if I believe the kidneys to be subject to more than passive congestion. I have seen a single dose of calomel salivate a nephritic. As a cardiac diuretic I have been in the habit of giving three grains of calomel every four hours, enjoining special care of the teeth. Given thus, it does not seem to affect the bowels. If it acts on the kidneys at all it usually does so on the second or third day, though I have seen the effect first appear on the fifth.

The diuretic action of caffeine and its first cousins, diuretin and theocin, is thought to be largely of vascular origin, though a direct action on the heart itself, cannot, I think, be as yet absolutely denied. Diuretin, in my experience, has never been of avail in renal dropsies. In those of cardiac origin its effect may be temporarily very gratifying. I have been led to attach value to its action or failure to act in cases of cardio-renal dropsy as an aid in deciding whether the cardiac or the renal element is predominant at a given time.

The objection to the alkaline diuretics is that their use runs counter to the dry diet which is ordinarily desirable when the blood mass is too great. Fluids are to be limited, as far as is compatible with the comfort of the patient, and the resourceful physician will secure tolerance and a greater fluid restriction than the routinist. Otherwise, diet should be nutritious, easily digested, moderate in amount. Gastric flatulence is to be avoided or counteracted.

There are cases, and times in the course of

cases, in which I believe wine or spirits, wisely used, to be of real service. Alcohol, unlike the rapid cardiac stimulants, such as camphor, aromatic ammonia, and ether, has some food value—calories, in modern parlance.

Direct stimulation of the myocardium is ordinarily desirable or necessary in conjunction with efforts to reduce the load. The members of the digitalis group are diuretics only in so far as they act on the myocardium, increasing its power, and thus raising the blood pressure. It is to this group that we look for direct and lasting myocardial stimulation. At its head stands, of course, digitalis, the many preparations of which and the dosage, varying in size and frequency, I pass over, simply noting the advance in recent years in standardizing digitalis. The only other members of the group worth mentioning here are strophanthin and apocynum. I have known each of these to succeed after digitalis had failed. I know no digitalis preparation which can produce such a rapid effect as strophanthin and cymarum when given intravenously, and perhaps, also, intramuscularly. The latter drug I have never used.

As a rule, it seems to me better to give only one of the members of the caffeine or digitalis groups at a time, pushing the dose until either the desired effect is produced, or there is evidence that the system is under its influence. This I think a great therapeutic law, applicable broadly to all active drugs. Exceptionally, however, judicious combinations seem to work better than the single remedy. Let me repeat here that we can only guess as to whether myocardial change is of such nature and extent as to be possible of repair or compensatory adjustment. Therapeutically, therefore, is it not wise to assume that some measure of such power is present, and try to call it forth? Is there one of us who has not found himself mistaken in both directions? In the long run, it is better to err on the hopeful side.

(b) The second major mark of cardiac failure is pain—angina.

This, as contrasted with edema, is suggestive of degenerative change, usually of the left ventricle, perhaps very local, and is the result of impeded coronary flow, to which spasm is superadded. Physical signs may be absolutely lacking, and diagnosis rest practically on a single symptom. I am inclined to think that angina is not recognized as often as it should be, some thinking that the pain cannot be of that nature unless agonizing. The pain is of all grades.

Although arteriosclerosis is common enough in hospital wards, we rarely there, or even in the out-patient department, see angina. The spasmodic element seems to be enhanced by a higher development of the nervous system than is common in hand workers. The treatment of anginal conditions falls into two natural divisions—that of the attack, mainly palliative, and that of the prevention of other attacks. A patient subject to angina should never be without a nitrite

ready for immediate use. I generally advise glonoin tablets as being, on the whole, more convenient. But amyl nitrite sometimes works better. It may be well to give a small dose before a necessary exertion, especially if this soon follows a meal, as a prophylactic against pain.

But the all-important therapy of angina, whether grave or relatively benign, is the regulation of the mode of life. The innocent and the grave cases vary more in prognosis than in therapy. Every effort should be made to avoid bringing on pain. In some cases it may be well to put the patient to bed for a week or two. Ordinarily, it is sufficient to limit activity to that which is compatible with comfort, remembering that upward inclines, a head wind, especially if cold, a full meal, straining at stool, venery and emotional vagaries are all inimical. More or less of these the intelligent patient finds out for himself. But it is our business to go into details, hoping through patient and persistent precaution to bring about, sooner or later, such adjustment or compensation in the heart as may markedly prolong life and render it very tolerable. Here, as in other aspects of the senile heart, the sum of small advantages may add up to very great therapeutic value. Diet, bathing, occupation, temperament, are all to be carefully considered.

It does not seem to me that tobacco should be absolutely and always interdicted. A sick man should not be deprived of any legitimate consolation, and the varying tolerance of tobacco by different people is notorious. A smoking doctor is likely to be more merciful than a non-smoker, but each should be on guard against his personal prejudices.

The details of medicinal treatment of true angina depend somewhat on its origin—whether this be infectious or non-infectious, and if infectious, whether of luetic or other origin. Medicinal treatment is usually of minor, though still of real importance. Strychnia is to be avoided as tending to heighten reflex excitability. Digitalis is indicated only in so far as myocardial failure is suggested by symptoms other than pain. Small doses of potassium iodide can seldom be harmful, and seem to be of value even in non-luetic cases. How far this value is suggestive in origin is hard to say. The average patient today is no less willing to carry out other directions when reminded three times daily that he is under medical supervision.

The action of glonoin is so transitory that its value between attacks is doubtful. If it be desirable, as I believe to be rarely the case, to try to secure constant reduction of blood pressure, sodium nitrite or erythrol may be used. With mannitol I have no experience.

The senile heart deserves a chapter to itself. An essential fact is that the changes which underlie it are degenerative, and tend to be progressive. We cannot hope for cure. Proverbially, we cannot add a cubit to our stature by taking thought. But we can add years of com-

fort and activity to life by taking thought for people with crippled hearts, especially if we succeed in inducing them patiently, persistently, cheerfully, intelligently to adapt their lives to their powers. For various reasons this may be, in whole or in part, impossible. We can only do our best. Pathetic, literally heart-breaking, is the case of the busy country practitioner with angina, dependent on his work for support, cranking and driving his own motor by night and day, at the beck and call of those far less ill than he.

DISCUSSION.

DR. JOHN SPROULL, Haverhill, Mass.: The duty of opening the discussion on the preceding papers was allotted to me by the chairman of this section. I do not think that there can really be any discussion, as far as difference of opinion is concerned, on the essential facts presented in either of the papers, so that the discussion can serve only to strengthen the presented ideas by perfect agreement or by presenting auxiliary facts and phenomena, showing the essentials from a different viewpoint. For that reason I can but state my own experience so far as related to the subject under consideration.

I do not know what influence digitalis has on the cardiac irregularity known as sinus arrhythmia, this being a physiological and not a pathological arrhythmia; I have not considered it of any importance apart from the question of diagnosis. I have not seen any benefit from digitalis in any form in premature contractions. I have many times, and do even now, occasionally try it out, believing that my observations, as to its lack of effect in previous cases, may have been fallacious, but I have always had to discard it as throwing an extra and useless load on the heart and digestive organs. My experience in pure paroxysmal tachycardia (of other than goitre origin) has been very limited, for in two years, I have seen but two genuine cases and neither was benefited by digitalis.

In heart block, I believe that in mild heart block, showing only some lengthening of the a-v interval, or an occasional dropped beat, associated with a weakened condition of the myocardium, digitalis may do good work, but in profound heart block, such as a three-to-one block, or in complete dissociation, I have not seen any benefit from its use, nor can I see the logic of its use in this condition. I have never been able to convince myself that any benefit could be derived from slowing a ventricle below 30 to 35 beats per minute, which is about the ventricular rate of complete dissociation.

I have had no experience with auricular flutter and very little with cases presenting pulsus alternans. Of the latter condition I have seen but three undoubted cases in two years and no benefit was derived from any drugs.

My experience with digitalis, however, is altogether different in auricular fibrillation, for it is

in this condition, above all others, that I have observed the most marked benefits from its administration. If one might talk of miracles, one might almost feel that in this cardiac irregularity digitalis works miracles. I have known its effect to be most marvelous, rescuing people who were almost moribund.

Its mode of action and its proper administration are so closely associated that one cannot discuss the one without touching more or less on the other.

Most cases of auricular fibrillation are seen in the condition of so-called dilatation of the ventricle, and how this condition of dilatation (which I believe is synonymous with exhaustion and loss of tonicity) is produced gives us some clue to the action of digitalis in this arrhythmia. The condition of dilatation of the ventricle is produced by the response of the ventricle to the excessive number of erratic stimuli originating in the auricle, and the action of digitalis would seem to be that of giving rest to the ventricle, either by blocking the passage of erratic stimuli by a selective action on the bundle of His, or by prolonging the refractory period of the ventricular muscle during diastole or by a combination of both methods. At least one may say that by digitalis the response of the ventricular muscle to the erratic stimuli originating in the auricle is prevented and the ventricle thus is rested and given an opportunity to recover its tonicity.

In the clinical use of digitalis, sufficient doses should be given to reduce the ventricular rate to somewhere near the normal and digitalis should be continued in dosage sufficient to maintain the normal ventricular rate, whether this entails its administration four times a day or once a day as long as the individual lives. By this method only can we, in my opinion, get the full benefit from the administration of digitalis, for auricular fibrillation is an incurable condition and the best we can do is to prevent its evil influence on the ventricle, and that we can often do by the continued administration of digitalis. It is well to remember that as far as we know at the present time digitalis does not have any such influence on the fibrillating auricle as it has on the dilated ventricle, and an auricle fibrillation once established is usually present for life, and that digitalis is useful not only as relieving the exhausted condition of the ventricle, but also in preventing the recurrence of this condition.

The prognosis of the various cardiac arrhythmias from two aspects:—

First. As to the cure of the condition.

Second. As to its effect on the life of the individual.

I can only agree with everything that Dr. White has said and state my own experience in some arrhythmias.

Premature contractions are usually not of serious import, if this is the only form of cardiac irregularity present. The prognosis of them, as far as life is concerned, may be disregarded, but

the prognosis as to their cure and removal is not very good in my own experience. I have had, however, two cases where premature contractions came in such frequency and there were such clutters of them that I believed that they contributed greatly to an exhausted condition of the heart muscle.

I have not seen enough paroxysmal tachycardia or auricular flutter to be able to give you my own results.

Of pulsus alternans I have seen but three undoubted cases in two years and they are all dead. My experience with heart block is that the underlying condition of degeneration of the myocardium or the associated arteriosclerosis should govern the prognosis. I do not think that the mere presence of heart block, except in so far as it is an indication of injury to the myocardium, can influence the prognosis. I feel hardly competent to speak as to the cure of heart block in young rheumatic hearts, for it can be only after an observation of a great many of them, for years, that one can feel that there has been complete recovery.

In elderly people with heart block and even complete dissociation, I have a number who have passed through the period of convulsions and are now living out their allotted span in comparative peace and comfort. One of these individuals showed convulsions due to heart block at 84 and is now enjoying 86 years of life.

The prognosis of auricular fibrillation is very complex and is dependent mainly on the response of the individual to digitalis.

As to cure of the fibrillation—that is impossible, for as far as science is concerned, at present there is no known drug which will change an incoördinate fibrillating auricle back to a coördinate contracting one.

The prognosis, as to the life of the individual, depends on two conditions:—

First. Is the fibrillation an abnormal rhythm associated with organic changes in other organs, as the liver and kidney?

Second. Do moderate and infrequent doses of digitalis keep the ventricle in condition?

Obviously it renders the prognosis much more serious if, in addition to the fibrillating auricle, one have organic changes in the kidney or liver, interfering with the functioning of the cardiac muscle, and obviously, also, if digitalis does not prevent the evil effects of the auricular fibrillation on the ventricle, then there is at present no other successful method of doing so, and the prognosis, as to the life of the individual, is rendered correspondingly more serious.

DR. F. W. PALFREY, Boston: The papers of Dr. Christian and Dr. White show adequately the close scrutiny that has been brought to bear upon the study of heart disease in recent years. Hearts which were formerly grouped as regular or irregular have, as has been repeatedly shown today, been separated among the different types

of irregularity. It has been shown that sinus irregularity does no harm; that the extra systole in itself is comparatively unimportant. Paroxysmal tachycardia is in doubt. Auricular fibrillation and flutter, heart block and alternation are of serious importance. But in considering these types of irregularity I think it is still to be remembered that an irregularity, like a valvular lesion, is only a factor in the total incompetence of the heart, and that it is from disturbance of contractility or tonicities, under which comes the dilatation of the heart long recognized, that cases of heart disease in majority die. Many heart cases die without incoordination of their chambers. Many cases of auricular fibrillation improve greatly, even though the auricles continue to fibrillate.

In decompensation with lessened ability of the heart to contract and loss of tonicity, the contraction of the heart at a disadvantage from distention of its chambers is a factor which should not be disregarded. In this connection I was glad to hear Dr. Shattuck's emphasis upon the value of venesection. Venesection is a measure which was formerly much used, but since its discontinuance following Virchow's condemnation of it in pneumonia, I am quite sure that the use of venesection outside of hospitals, and perhaps even in them, is too infrequent. Venesection perhaps has become a measure against which there is popular prejudice. But those who have used it in acutely incompetent hearts I think will agree with me that it is a measure which ought to be emphasized and more widely used than it is.

DR. JOSEPH H. PRATT, Boston: I think that many of us do not realize the frequency of these conditions which we have heard discussed this afternoon. The terms used—auricular fibrillation, auricular flutter, extrasystoles, and pulsus alternans—are new, but the conditions are old, and we have all seen many examples of them, but they passed unrecognized because we did not use the newer methods of study. Now, I made an interesting clinical investigation this spring with the aid of four senior students. In the outpatient department of the Massachusetts General Hospital, through the courtesy of the staff, I was allowed to examine and study all cases with suspected heart disease admitted to the male and female medical rooms. During a period of two months we made routine examinations with the polygraph and the telerradiograph, and through the cooperation of Dr. White many of the cases were examined with the electrocardiograph. During that period we saw and examined a hundred and fifty patients with cardiac disease, and among these we found no less than sixteen per cent. with auricular fibrillation, sixteen per cent. with extrasystoles, two per cent. with auricular flutter, four per cent. with pulsus alternans, and ten per cent. with delayed conduction or partial heart block. There were fifty-eight cases, that is, over thirty-three and a third per cent. of all the patients that came there, who

had arrhythmia of one sort or another. In forty-one per cent. of these cases, the irregularity was due to auricular fibrillation.

Now these figures show the frequency with which these conditions occur in ordinary daily work. Many of the patients had slight evidence of cardiac disease. I remember very well the first day of our work, a woman came in who was slightly short of breath, but on the ordinary physical examination nothing abnormal was found about her heart. Simply as a routine procedure I made a polygraph-tracing and found there was delayed conduction. This observation was confirmed by Dr. White with the electrocardiograph. The delayed conduction meant that the patient had a myocardial disease and justified the diagnosis of chronic myocarditis. This could not be recognized in any other way.

I think that the polygraph should be used by every physician who intends thoroughly to study his cases of cardiac diseases. With a Dudgeon-sphygmograph provided with a time marker, a great deal of information can be obtained which is impossible by palpation of the radial pulse. Dr. Christian justly emphasizes the importance of educating the finger to recognize auricular fibrillation, but he must admit that there are some cases of auricular fibrillation in which the interval between successive beats is so slight that it cannot be recognized by the unaided finger. In the diagnosis of pulsus alternans, a radial pulse tracing is necessary because many of the cases of pulsus alternans will not be detected by the palpating finger. Dr. White has clearly shown that the recognition of pulsus alternans is important, because this condition indicates a serious weakness of the heart muscle. With the polygraph, delayed conduction from the auricle to the ventricle can be made out, and this may render possible the diagnosis of acute or chronic myocarditis that might otherwise escape detection.

The frequency of myocardial disease was another point brought out by our study. It was only a few years ago that teachers and text-books paid very little attention to myocardial disease in the absence of valvular disease. By the use of modern methods, we found that primary myocardial disease, with intact valves, is far more frequent than is commonly thought. There were no less than sixty-three cases of cardio-sclerosis in our series. Only seven of these had nephritis. There were more cases of primary myocardial disease than of valvular disease.

I think the recognition of pulsus alternans, which occurs frequently after extrasystoles, as Dr. White has shown, is of distinct value in diagnosis and prognosis. If I am not mistaken, he has observed more cases of pulsus alternans than any other investigator has reported.

Just a word in regard to treatment. Dr. Christian has shown very clearly what digitalis in large doses can accomplish. He has used from the opening of his clinic active preparations of digitalis, and in larger amounts than have been

employed by most of the physicians in this vicinity. In 1910 I reported before this section a study of the preparations of digitalis used in Boston in the hospitals and dispensed by leading druggists. These were carefully tested physiologically in the laboratory and only one single specimen was found that was active in the ordinary doses. At that time I called attention to the titrated powdered digitalis leaf prepared by Caesar and Loretz of Halle, Germany. I have found it as satisfactory as digipuratum for general use and far less expensive. I should like to know what preparation Dr. Christian is now using. In private, as well as in hospital practice only preparations made from active digitalis leaf of known strength should be used.

DR. CHRISTIAN: In regard to the question of Dr. Sproull, as to whether digitalis will stop pulsus alternans, usually no, sometimes yes. The patient who responded so well to digitalis, whose chart and tracing I showed you, had marked pulsus alternans on the 11th. The chart began on May 10, and I took tracings of the patient on yesterday, and there is no trace whatsoever of pulsus alternans. That is the exception. Usually the pulsus alternans will resist the digitalis, but the heart will become functionally more efficient, except in those cases in which the myocardial disease is extensive, and I spoke of this in cautioning one against pushing digitalis when a patient of this group is not under close observation, on account of the occasional rapid change from therapeutic action to marked toxic action. Usually the digitalis does not do away with the pulsus alternans.

In regard to the venesection that Dr. Shattuck and Dr. Palfrey spoke of, I should like on my part to emphasize that as a very important procedure, and point out to you the great ease with which you can bleed a patient at the present time. With the methods that we use for obtaining blood for a Wassermann reaction it is possible to bleed a patient without any incision and practically without any pain. You can bleed a patient four or five hundred c.c. with the utmost ease, and if you have any doubt as to whether you should make your patient anemic or not, don't bother about it. It is quite possible later to transfuse the patient, and restore the amount of blood if necessary. There are a great many immediate advantages in venesection.

In regard to Dr. Pratt's question as to the preparation of digitalis which we use. We used Caesar and Loretz's standardized digitalis leaf, but it became a little more difficult and expensive to obtain that on account of the war conditions, although it is still possible to get the preparation. I thought it was worth while on our part to see what we could do with home products, so I had our pharmacist write to one of the well-known manufacturers of drugs and tell him that we wanted a specimen of powdered digitalis leaves, and we wanted him to send us an effi-

cient preparation because we were going to test it in the laboratory, and we were going to test it in the wards, and if it wasn't good we were going to send it back and would not buy drugs from him. The result was that the first bottle of powdered leaves, when we tested it out in contrast with Caesar and Loretz's preparation on frogs, seemed just a trifle less efficient, but really very little different. We used it in the clinic and got just as good results on our patients as we had gotten before with Caesar and Loretz's leaf.

We have reduced our digitalis therapy to very simple terms in our own clinic. We use but two preparations by mouth, powdered leaves and infusion. We use one preparation intravenously (strophanthin) when we want to get immediate effects, and occasionally, if for some reason we want to use a subcutaneous intramuscular dose, we use a third preparation (liquid digipuratum) for that. We do not use the tincture for this reason: the infusion can be made in a very short time. The tincture has to percolate for twenty-four hours after it begins to run, and this is a little bit more trouble and takes a little bit more time. I believe ordinary tincture that is put on the market is very often inefficient. If you know that a druggist has got a good preparation of powdered leaves of digitalis, send all your patients to that druggist and have him make up the infusion every time the patient brings his prescription, or make the pills each time. As far as the leaves are concerned, you can use them as powder to put on the end of the patient's tongue, to take down with water. Until we know more about the specific action of the various alkaloids that go to make up digitalis, and I don't think we know practically anything about them now, you can throw into the wastebasket all the literature about new digitalis preparations and stick to these three or four forms. If you select the proper kind of a patient on the basis of type of irregularity, and give your digitalis in sufficient dosage you will get such results that you will feel pretty confident that digitalis is a good effective drug, and one very well worth having at your beck when you have a patient to treat with cardiac decompensation.

DR. WHITE: I must take exception to one remark of Dr. Pratt's. I have records at present of eighty-three cases of pulsus alternans. In 1913 Mackenzie had records of over a hundred. I want to emphasize the importance of the finding of pulsus alternans as evidence of myocardial weakness. It shows damage, or at any rate exhaustion, of the myocardium of twice the importance of that shown by absolute irregularity of the pulse. That is, *pulsus alternans* is twice as significant an index of cardiac exhaustion as is the absolutely arrhythmic pulse of fibrillation of the auricles.

Reports of Societies.

TRANSACTIONS OF THE THIRTIETH ANNUAL MEETING OF THE ASSOCIATION OF AMERICAN PHYSICIANS.

Held at Washington, D. C., May 11, 12, and 13, 1915.

The President, Dr. S. J. MELTZER, called the meeting to order at 9.45 a.m., May 11th.

THE PRESIDENTIAL ADDRESS.

After reference to the deaths during the past year of Dr. Samuel C. Chew, of Baltimore, Dr. Morris Longstreth, of Cambridge, Mass., Dr. Geo. L. Peabody, Newport, R. I., and Dr. W. E. Fischel, of St. Louis, Mo., the address dealt with certain policies and tendencies within the Association and indicated dangers to be avoided and ends to be attained.

The remarkable work accomplished by the American Medical Association, notably through the Council on Medical Education and the Council on Pharmacy, was alluded to and a plea made for more active participation by greater numbers of men of the true scientific spirit in the organization work of the American Medical Association as well as in the scientific work of the Sections.

The American Medical Association had come to exert a most remarkable influence upon the medical profession of this country, and its Journal had grown to be one of the best medical periodicals in the world. What had the Association of American Physicians contributed to this attainment? So far as the speaker could observe, nothing more than the indirect stimulus of its mere existence.

Reference was made to the changed scope of the Association's work; whereas it formerly obtained its broader point of view by virtue of its contacts with other units of the American Congress of Physicians and Surgeons, now the Association itself had the advantage of numbering in its membership not only internists, but also pathologists, bacteriologists, physiologists, pharmacologists, hygienists, and men interested in the public aspects of preventive medicine. This proved to be not an unmixed blessing; the program too often contained titles far removed from practical medicine and more appropriate for presentation elsewhere. Papers presented before this Association should always be distinctly related to clinical medicine; no papers should be presented unless related.

But, with all its bright future, clinical medicine will not gain its best advantage except by the close cooperation of clinicians and investigators. Diseases are experiments which nature makes on men and beasts. The expressions of disease, the steps of these experiments in nature, as observed by trained interpreters, will always be the best teachers of future physicians.

Clinical medicine does not consist of diagnosis and therapy alone. Great physicians are often great investigators also; unless this were so we should not now speak of Graves' disease, of Bright's disease, of Addison's disease. It was the physician Oliver who first noticed the rise of blood pressure after the administration of adrenal substance; but it was his cooperation with physiological chemists that resulted in the identification of adrenalin. It

is thus that the cooperation of both kinds of workers will assure the future of the Association.

Some have objected that the papers tend to go over their heads; but the program usually represents the present stage of medical progress, and if the papers go over the heads of any, the fact merely demonstrates that these have ceased to progress. Thus, the objection is not a valid one, otherwise all progress ceases.

After the transaction of business, the scientific program was taken up.

2

"Important Contributions to Clinical Medicine during the Past Thirty Years from the Study of Human Blood Pressure." By THEODORE C. JANEWAY, Baltimore, Md.

Clinical observations upon blood pressure in man had not been made at the time of the foundation of this Association.

In Flint's Practice of Medicine, published in 1886, there is a passage referring to an increase of blood pressure in cases of small granular kidney and in cases of apoplexy. This showed an appreciation of the problem from facts learned by the unaided senses. A little later, Delafield, in this Association, spoke of cases with arterial narrowing, with increased intravascular tension, but no measurements of pressure were alluded to. In 1889, Stengel read a paper on Athletics, but there was no mention made of blood pressure observations.

In 1903, Cabot presented observations on blood pressure in man, and in 1904, there was a second paper by Cabot on observations of blood pressure by the sphygmomanometer. Since then the programs have always contained some titles bearing on this subject.

What has been the real gain? There has been developed an easily available method by which any physician can gain by measurement essentially accurate information concerning both the systolic and diastolic pressures in the arteries.

A sketch of the development of the sphygmomanometer was given, together with the notable names connected with the development of present knowledge of the subject.

The development of this method of clinical study has revolutionized the diagnosis of chronic Bright's disease, in contradistinction to the statement in Flint's Practice that the diagnosis of chronic nephritis depends upon the urinary findings. It has made a clinical entity of essential hypertension, of cardiovascular disease. It has disclosed the high pressure of the celampytic state, and the low pressure of amyloid kidney. It has revealed the curious fact that in aortic regurgitation the pressure is higher in the leg than in the arm.

The study of average human blood pressure in connection with life insurance statistics has constituted an important and distinctively American line of research; Fisher's statistics are most important and indicate the normal increase of blood pressure with age. The tendency is to agree with

Lauder Brunton and Cooke that 135 mm. to mid-life and 145 mm. thereafter mark the limits of normal maximum variations in man. We have learned, in individual cases, however, not to view hypertension with so serious a prognostic eye.

From the therapeutic standpoint, the recognition of the greater importance of cardiac conservation and adequate circulation than reduction of abnormally high pressure has been a very important contribution to our knowledge. The beneficial effect of digitalis in maintaining compensation in these states is also a valuable contribution. The study of the effects of caffeine, strychnin, and other allied heart stimulants in connection with observations of the blood pressure has resulted in disillusionment with respect to the value of these agents.

Perhaps the most important of all the contributions to clinical medicine growing out of the study of human blood pressure have been the theoretical considerations having to do with the origin and explanation of the degenerative cardiovascular diseases, and these considerations must continue to be the basis of further study.

4

"Observations on Dyspnoea in Cardiac Disease." By FRANCIS W. PEABODY, Boston, Mass.

The observations were made to ascertain the rôle played by acidosis in the production of the dyspnoea of cardiac disease. The conclusions reached were:

a. Acidosis plays an insignificant part in the dyspnoea of simple cardiac disease.

b. Acidosis is a more important factor in the dyspnoea of cardio-renal disease.

The second conclusion might be expected from the facts that acidosis is often present in cardio-renal disease and that dyspnoea is often present in the absence of cyanosis. To these facts may be opposed the objections that the acidosis is usually slight and that the dyspnoea is clinically different from the dyspnoea of diabetes; in cardio-renal disease the dyspnoea can be compared with exercise dyspnoea.

In making the observations a respirator was used and, by rebreathing, the CO_2 content of the expired air was increased. The respiratory products were measured and the stimulating effect of CO_2 was noted. Respiration in most persons is increased so that pulmonary ventilation is doubled when the CO_2 reaches 4½% or 5%. In mild cardiac valvular disease, subjects behave in precisely the same way; in cardio-renal subjects, however, pulmonary ventilation is doubled when the CO_2 reaches 2½% or 3%. This difference in behavior is explainable on the basis that the reaction of the blood is more easily disturbed in cardio-renal disease on account of the high acidity induced by the acidosis. The experiments were further carried on to note the influence of alkalis in controlling the dyspnoea.

5

"Stokes-Adams Syndrome with a Remarkable Delay in the A-V Conduction Time." By W. S. THAYER, Baltimore, Md.

The woman upon whom the observations were made was 50 or 55 years of age, the mother of several children. She had suffered with attacks of dyspnoea for several years. After a series of attacks characterized by intermittent pulse, she became unconscious and the pulse became very slow. When seen by the writer she had a perfectly regular heart beat, rate 35 per minute.

Examination with polygraph indicated that she was suffering from a total bradycardia with the A-V wave 0.7 second in duration. Electrocardiograms were made which upheld the suspicions excited by the polygraphic tracings, viz.: that the heart was beating with one auricular to each ventricular contraction, and with the most remarkably prolonged p-r period of 0.68 second. After exercise, the pulse rate fell from 35 to 28 per minute and by polygraphic tracings the A-V wave was now found to be 0.8 second, and later the A-V wave reached the unprecedented duration of nearly 0.9 second.

It was desired to ascertain the effect of atropine but the patient was hypersensitive to the drug and its use had to be abandoned. There have been a number of similar seizures since but the patient has utterly refused to allow further study.

This case at first glance would seem to be one of ordinary heart block with dissociation; but on study it was found to be one of total bradycardia. So far as known, there is on record no other case with such a long pause between the auricular and ventricular contractions. Two polygraphic tracings taken 6 weeks apart with identical curves could hardly be a coincidence.

"A Review of the Advance in Our Knowledge and Treatment of Cancer in the Last Thirty Years." By FRANCIS C. WOOD, New York, N. Y.

Papers dealing with the origin and cause of cancer have been notable by their absence from the programs of this Association for a long time. It is interesting to note that Delafield made an important contribution to the knowledge of cancer many years ago which remained unpublished until discovered by the writer in Prudden's laboratory. It described clearly and minutely the structure of a new variety of neoplasm which afterwards was recognized by the Germans and by them named chorioepithelioma.

Little has been accomplished since the early days of cancer investigation; many efforts have been made, but few discoveries can be recorded. The work of Virchow, Waldeyer, Thiersch was all published before 1885 and this work fairly settled the classification of malignant tumors. Since that time we have learned much more about the details of cancer, but there has been no advance in the clinical

knowledge of cancer, hence the need of study by the experimental method.

Perhaps the first step of advance to be recorded was from Sweden, where Jensen succeeded in the artificial cultivation of neoplastic tissues. He brought out many important points, but at once fell into the error of trying to find a means of cure by the production of an antiserum; he was not aware of the possibility of spontaneous cure of mouse tumors and attributed the recovery of some of his mice to the antiserum. This mistake was carried on by subsequent investigators and has been the cause of much lost time and labor. The next step was the observation by Gaylord of spontaneous recovery of mouse tumors; this observation was accepted by Jensen who admitted that the claims for his antiserum were probably based on similar recoveries. Gaylord observed further the subsequent immunity of such recovered mice to tumor inoculation. The paper made a plea for the general adoption of the valuable method of charting developed by Gaylord and his associates.

In 1905-1906 Ehrlich announced that mice have certain tumors which may be observed undergoing transformation into sarcoma. This transitional period covers about 50 days in mice, a period biologically equivalent to about ten years in man.

In 1908 Bashford noted the production of immunity against tumor formation by injections of tissue extracts.

In 1910 Russell showed that tumor production depends upon vascularization of tissues.

In 1915 Rous demonstrated that chicken carcinoma is transmissible by inoculation not only of the tumor tissue but of filtrates from such tissue. Rat and mouse tumors can not be thus reproduced.

Lambert and Haines have found that tumor cells of the mouse will grow in mouse blood and equally well in the blood of immune mice; thus showing that cancer immunity in the mouse is not a serum reaction.

Murphy, at the Rockefeller Institute, has destroyed the bone marrow of experimental animals by x-ray exposures and thereafter has been able to reproduce foreign tumors in such animals, thus suspending the rule that tumors will not grow in a foreign host. It may be inferred, therefore, that at least part of the natural protective mechanism against tumor formation is an attribute of the bone marrow.

Febiger has shown that tumor formation in the stomach of animals may be caused by feeding certain parasites. The writer's own work, however, has demonstrated that the same appearances may be provoked by the ingestion of various irritating substances.

Tissard has pointed out that squeezing or massaging mouse tumors will provoke the formation of numerous metastases, an observation with obvious significance.

This is the meagre fruitage of an immense amount of work; much more needs to be done and it must be done with the realization that the mouse is the test tube for the study of cancer and that all results must be rigidly checked up with all the known facts from whatever source derived.

The therapy of cancer has made no progress. Surgery is still the best hope we have. Radium and x-ray therapy are more and more disappointing. The x-ray cures are found to be after all merely remissions, the x-ray having done no more than to

provoke a temporary suspension of growth or to impose a very slow rate of growth.

"A Case Illustrating Some of the Limitations of Physical Examinations of the Thorax and also those of an X-Ray Examination." By FRANCIS H. WILLIAMS, Boston, Mass.

The case was presented to point out the fact that after the diagnosis of thoracic aneurysm has been excluded by physical examination, the x-ray plate may occasion a change of ideas; also, that after the diagnosis of thoracic aneurysm has been made from the x-ray plate, physical examination may alter one's opinion. In pulmonary tuberculosis, these same propositions may also be advanced.

Two radiographs were exhibited, both made from the same patient, one having been taken in 1899 and the other in 1915. While the x-ray diagnosis does not alone suffice for final conclusions, here is an instance in which a mass is disclosed which gives rise to no physical signs whatever. The diagnosis is still unmade.

GROUP ON BLOOD AND BLOOD DISEASES.

"A Method of Determining Total Plasma and Blood Volume." By L. G. ROWNTREE, N. KEITH, and J. T. GERAGHTY, Baltimore, Md.

and

"A Simple Method of Determining Variations in the H ion Concentration in the Blood." By L. G. ROWNTREE, McKIM, MARIOTT and R. L. LEVY, Baltimore, Md.

Growing out of former studies on renal functional tests, two new methods of clinical investigation have been developed.

1. The determination of total plasma and blood volume.

The method consists of injecting into a vein a given quantity of a non-toxic, non-dialysable red dye; in 3 and 6 minutes, specimens of blood are taken and the degree of dilution of the dye determined. For this determination a standard is necessary and such a standard solution is prepared by securing some blood before the dye is injected, and diluting an amount of dye equal to the dose to 4% of the body weight, using for the diluent 1 part serum and 3 parts salt solution. When the blood is taken after the injection of the dye, the serum is separated, diluted and compared with the standard solution: from this point the calculation is easy.

Curves have been constructed to show the loss of the dye from the human circulation and it has been found to be only 1% to 2%. It leaves the blood of dogs very late. The dye cannot be found in the tissues and it is not believed that it goes into the blood cells, either red or white.

In duplicate determinations, figures have been obtained with results coinciding within 100 cc. The average figures in normal individuals indicate that the blood volume should be 85 cc. per kilo or about 1/12 the body weight.

In essential hypertension and in diabetes the blood volume has been found to be normal. In pregnancy there is a large increase in the blood mass which does not disappear until 7 to 10 days

after delivery. This would seem to be a physiological preparation for hemorrhage.

2. Determination of the H ion concentration in the blood.

The method consists of adding an indicator (phenolsulphonphthalein) to the dialysate of blood serum and comparing with a solution of known H ion concentration. The method of preparing the dialysate is described in the paper.

The normal figures for H ion concentration are 7.6 to 7.8. Many cases have been studied, among them 20 cases of acidosis, all of which have shown a concentration toward the acid side, as low as 7.0.

In experimental acidosis, the readings went as low as 6.7, at which point the animals died. In alkalosis, the readings may go up to 8.0 or 8.1 when the animal dies.

By this method the buffer values of the blood may be determined and in acidosis the buffer values are very low. It is an easy method to study both acidosis and alkalosis from the blood side.

"Metabolism Studies Before and After Splenectomy in Congenital Hemolytic Jaundice." By SAMUEL GOLDSCHMIDT, O. H. PERRY PEPPER, and R. M. PEARCE, Philadelphia, Pa.

The patient had a severe anaemia from birth with the later usual history. Metabolism studies were made both before and after splenectomy. The blood picture after operation showed marked improvement.

In general the studies indicated a tendency to lose N before splenectomy and to retain N afterward; the operation seemed to restore the capacity for nitrogen utilization. With respect to uric acid, there was a high elimination before splenectomy with a drop of 47% in uric acid output after the operation.

The utilization of iron has been said to be low before and high after splenectomy in such cases; the present studies indicated that the iron elimination before splenectomy was 50% above the intake of this element and that after the operation the iron elimination was greatly reduced. Moreover, after splenectomy there was a reduction of 90% in the urobilin elimination in the feces.

What do these figures mean? They seem to support the improved blood findings after splenectomy as evidence of the real benefit of the operation. Banti had two cases in which the difficulty in nitrogen utilization was noted and in the case here presented the same observation was made. In these blood diseases there seems to be engaged some toxic agent which interferes with the ability to build up proteins. Removal of the spleen seems to remove the toxic agent or the sources of it and in addition the hemolytic agent is removed as well.

18

"On Plasmapheresis." By J. J. ABEL, B. B. TURNER, E. K. MARSHALL, JR., and P. D. LAMSON, Baltimore, Md.

Among the many points of view from which one may study the minute structure of the blood, the relation of cells to plasma led to experiments which consist of the removal of the plasma of withdrawn blood and the return of the cells to the circulation, a process to which has been given the name plasmapheresis. The method is as follows: an animal is bled very freely, almost to fatal exsanguination, the blood caught in a solution of hirudin to prevent coagulation, diluted to double its volume with Locke's solution, centrifugalized and the supernatant plasma discarded. The cells are now diluted to the original bulk of blood with Locke's solution and restored to the circulation of the animal. In this manner one can replace a very large proportion of the blood plasma by a solution such as Locke's with no apparent injury to the animal; and this may be done repeatedly from time to time still without injury to the animal.

Tables are given showing the changes in blood count; changes in the protein of the blood, etc. Blood pressure estimations were made and it was found that the low pressure of the exsanguinated state was well restored upon the return of the fluid to the vessels.

In the work it has been found that leech extract is not toxic, at least to the extent in which we use it. But since the war, the supply of leeches has been interrupted and a manufactured hirudin has been tried; this product is very toxic, quantities as small as 10 mg. being sufficient to kill animals with symptoms of great shock.

19

"The Preservation in Vitro of Living Erythrocytes." By PEYTON ROUS and J. R. TURNER, New York, N. Y.

There are several practical purposes involved in attempts to preserve intact mammalian red blood cells: for culture materials in the cultivation of plasmodia; for readily available indirect transfusion material etc.

It is interesting to find why erythrocytes last such a short time outside the body in view of their relatively long life in the body. In the work herein reported, washed cells were first used, but were found to disintegrate very early. It was determined that the plasma exerts a protective influence on the cells; for while washing in the centrifuge causes an injury to cells with the production of hemolysis, the addition of citrated plasma prevents this injury. It was found also that gelatin in the proportion of 1% in Ringer's or salt solution will protect the cells for a long time. Cells were tested by shaking to compare their fragility when thus treated with their fragility to hypotonic salt solution: there was no relation between the degrees of fragility, though bloods differ in their behavior in this regard. Human blood cells can be washed without injury.

Cells are protected but not preserved by gelatin; the addition of glucose or saccharose, however, to gelatin Ringer's solution will preserve the cells for a long time.

Cells that have kept several weeks take up and surrender oxygen normally; do not clump or show morphologic change; behave normally in the Wassermann reaction: are these cells really alive? Rabbits were exsanguinated and preserved blood used to supplant that withdrawn; the animals were fully restored and behaved normally after the operation. Many tests corroborated this experience. Rabbit

blood can be kept alive at least two weeks. Human blood can be kept for several weeks in dextrose-gelatin solution.

20

"Clinical Studies in Blood Transfusion." By E. LIBMAN and R. OTTENBERG, New York, N. Y.

The studies have been made in various forms of disease.

In the simple hemorrhage, the results of transfusion were uniformly good, especially in hemorrhage of gastric and duodenal ulcer. Transfusions made during the progress of the hemorrhage acted equally well as when made after the accident, and seemed to encourage spontaneous arrest of the effusion.

In six cases of dysentery, transfusion was followed by marked improvement.

In seven cases of typhoid hemorrhage, nine transfusions were done with two recoveries.

Transfusion is useful in operative work, both before and after operation; but it is of no help in surgical shock.

In purpura hemorrhagica, transfusion was done twelve times in nine cases; six cases recovered, the two deaths being in cases occurring shortly after pregnancy. In this disease, transfusion appears to have a direct curative value.

For hemophiliacs a donor should be picked in advance for possible needs. For prophylactic purposes a small transfusion every few months may be useful. Transfusion is much more helpful than the injection of serum.

For the treatment of postoperative hemorrhage in obstructive jaundice, transfusion was not of material benefit. The suggestion was made that in this condition there should be a preliminary bleeding with a large transfusion from several donors.

In pernicious anaemia and leukaemia the results were not uniformly good. In twenty-five cases of pernicious anaemia, fourteen showed for a time progressive improvement; eight of these are alive at the present time, but they all present evidences of blood trouble. In eleven cases transfusion was of no avail; two cases were also splenectomized without improvement.

The details of one case were given: in this case there were four transfusions, followed later by splenectomy; a remission then took place.

The conclusion was reached from all the experience that transfusion does more than anything else to abate the blood symptoms. It is important to try several donors when no improvement follows one or more transfusions from a single donor.

The effect of transfusion on the symptoms of pernicious anaemia were summarized thus: the appetite improves, the mental symptoms grow better, the glossitis clears up, and the blood picture improves; but the spinal cord symptoms do not improve. There is fever in 50% of the cases; some become afebrile after transfusion. The fever may be due to toxic causes or to the anaemia.

In this disease splenectomy is advisable; if no remission occurs after the operation, then transfusion should be done; or if remission does not follow transfusion, then splenectomy should be resorted to. We may thus determine the relative values of the two methods of treatment.

In leukaemia, there was some improvement following transfusion in a number of cases; but it was not lasting.

In acute infections, transfusion has no very large field of application. Patients may be helped along by it at times, but the best results are to be had in long continued subacute infections. In endocarditis with retention of infection transfusion does good only to the extent of prolonging life for a time.

The conclusion was reached that the Unger method of direct transfusion and the Weil citrate indirect method are the best and will supersede all others.

21

"The Progress Achieved During the Past Thirty Years in the Prevention and Treatment of Diphtheria." By W. H. PARK, New York, N. Y.

In the thirty years just past we have witnessed the growth and decay of the hope that by isolation and terminal disinfection the incidence of diphtheria might be reduced. There has been no such result except in the limitation of the spread of the disease in families and other small groups. The total mortality is just as high as ever, restricting comparisons, of course, to the antitoxin era.

Much work in other directions has been done meanwhile which brings us to another era.

Passive immunity we know will protect for a few weeks; 1000 units of antitoxin will confer immunity for about two weeks. We know too that this immunity may be repeated, but that its duration is curtailed after secondary injections. The short duration of passive immunity led to efforts to increase it. Three years ago Behring used a toxin-antitoxin mixture for this purpose. For 18 years producing laboratories have known that such mixtures were useful in speeding and increasing the antitoxin yield of horses. Theobald Smith suggested the use of this method in children, but Behring was the first to apply it. Other workers have, however, found limitations to the method in the fact that individuals who have no natural immunity are with great difficulty made immune, while indeed 25% of the natural non-immunes cannot be made immune at all. For practical purposes, passive immunity remains for the present the most used prophylactic measure.

Efforts have been made to see if bacterial vaccines would increase immunity, but with little success. Tests by fixation and by agglutination showed few antibodies. Present efforts have to do with attempts by the combination of toxin-antitoxin and vaccine therapy to increase both antitoxic immunity and antibody immunity.

In antitoxin therapy, we began with weak units and moderate doses; as the units have grown stronger, physicians seem to have correspondingly increased the dosage. Recently there has been much variability and uncertainty as to dosage and it is the fashion in some localities to give exceedingly large doses. It would seem that physicians have a very hazy idea why they employ a given dose of antitoxin. It is not well known that antitoxin is slowly absorbed and that it persists in the body a very long time. It has been shown that instead of any necessity of giving large doses of antitoxin to combat increasing doses of toxins as a matter of fact there are seldom present at one time more than 100 units of toxin even in the most severe cases. In fact it may be said that 1000 units of antitoxin given intravenously has an equal effect to 20,000 units given under the skin. The inference

from this statement is patent, and occasionally the intravenous method of administration should be used; but so far as the life of the diphtheria patient is concerned, only in a few cases can it be shown that the method of administration of antitoxin is of much moment. The Schick reaction aids in the appreciation of the effect of antitoxin. A single dose of antitoxin should be sufficient; a second dose is a reflection on the first.

With regard to prophylaxis it should be remembered that Schick has found that one half of the people will be found protected against diphtheria by natural immunity.

"Present Status of Specific Treatment of Epidemic Meningitis." BY SIMON FLEXNER, New York, N. Y.

23

"The Treatment of Tetanus by Antitoxin Given Intraspinally." BY MATTHIAS NIELL, JR., New York, N. Y.

(Journal A. M. A., June 12, 1915.)

As successful as antitoxin has been in the prophylaxis of tetanus, it has been disappointing in treatment. One reason for this is that the diagnosis is usually made too late.

The prevalent advice heretofore has been to give a large intravenous dose of antitoxin, with later subcutaneous injections. This method has been very disappointing in practice, as has been said.

Experiments were made to ascertain the value of intrathecal administration of antitoxin. Guinea pigs were given twice the minimum lethal dose of tetanus toxin; they died in three days. Pigs treated thus were given antitoxin by injection into the heart cavity; they died in 5 to 8 days. Tetanic pigs treated by injecting antitoxin into the sciatic nerves did no better. But pigs treated by injecting 1/20 the dose of antitoxin used in the other animals into the spinal canal recovered. Several pigs were allowed to grow so tetanic that they were twisted into grotesque shapes; out of six treated by intraspinal injections of antitoxin, three recovered.

Since these experiments there have been twenty human cases in and around New York City. All were treated with intrathecal injections of antitoxin and 16 out of the 20 recovered. The method of treatment recommended is to give 3000 to 5000 units into the spinal canal, diluting the serum 10 to 20 cc to make it thin and easily diffusible; posture is not required to assist diffusion. In addition, 10,000 units should be given intravenously. The intraspinal injection should be repeated in 24 hours and, if necessary, the intravenous injection should be repeated also. By this method the mortality of tetanus has been reduced to 20%.

24

"The Treatment of Acute Lobar Pneumonia by Specific Methods." BY RUFUS I. COLE, New York, N. Y.

A specific therapy for acute lobar pneumonia has been an object of eager search throughout the life of this Association. Has any progress been made toward the discovery of a specific remedy?

The paper relates the steps in this direction from the work of Fränkel, who was able to develop a certain resistance in animals, to that of Morgenroth who observed the destructive effect of ethyl hydrocuprine upon pneumococci in vivo.

One of the baffling difficulties is the fact that it is necessary to know the exact causative organism active in a given case; moreover, if it is determined that the pneumococcus is the predominant organism, it is still necessary to determine the type of pneumococcus; for four large groups of this organism may be distinguished. The disease then cannot be regarded as a pathological entity but must be approached by a specific etiological study.

Much of the work upon the problem of the specific treatment of lobar pneumonia has been directed toward the development of a vaccine therapy, following the lead of Sir Almroth Wright. But study of the problem indicates that there are two immune processes to be reckoned with: A body or somatic factor and a serum or passive factor. Active immunization is best accomplished by the disease itself. Workers with sensitized vaccines have found that their apparently beneficial results have not been due to immunity invoked by the vaccine but to immune substances present in the vaccine. The literature shows no good results from vaccine therapy, and this may be the more readily understood since we have come to know that the use of pneumococci of type I could have no helpful influence in a pneumonia due to pneumococci of type II.

Attention has thus been concentrated on devising means for producing passive immunity. The paper gives facts based on animal experiments to show that there is good reason to expect good results in this way. Immune bodies have been found in animal sera long ago; but failures to accomplish much with these sera have been due to the lack of knowledge hitherto of the different types of organisms with which we have to deal; insufficient doses of organisms have been used in inoculations for the production of immune sera; and too little serum has been used in the treatment of pneumonia. It is now easy to recognize the different types of organisms and it has been done practically in a number of cases with the development of truly specific sera. Types I, II, III, and IV are recognized. It has been found impossible to produce an immune serum for type III, and the use of such a serum in type IV is impracticable because it is so variable. Thus serum therapy is reduced in application to cases due to pneumococci of the types I and II. Serum therapy in 46 cases of pneumonia due to type I organisms had a mortality of 8%; of the fatal cases 1 died of pulmonary embolism and 2 had treatment only a few hours before death. These cases, of course, are insufficient to prove anything; conclusions must be based on experimental evidence and not on statistical clinical evidence.

With regard to chemotherapy, it is known that sodio-oleates are antagonistic to the development of pneumococci, but it is not possible to use these substances therapeutically. Morgenroth has shown that ethyl hydrocuprine is specific against pneumococci; but in mice it is necessary to give a large dose—approaching the toxic point—and to give it very early. To give in man a dose proportionate to that necessary in successful experiments on mice, it would be required to exhibit about 70 gm., whereas the administration of 1.5 gm. has been known to cause amblyopia.

(To be continued.)

EUGENICS AND PRESENT-DAY WARFARE.

THE application of the Darwinian theory of the survival of the fittest in the case of the individual to a race, as has been done by Bernhardt and others, that in war the stronger races survive and the weaker perish, the whole human race profiting thereby, may have been a tenable hypothesis in the time of the Germanics and the Goths. In those days of primitive warfare the weakest nations were destroyed and the strongest survived. When gunpowder was invented and man could kill his adversary from a distance, and later, with the advent of smokeless powder, without disclosing the location of the destructive agent, all this was changed.

The Chinese minister at Brussels is reported to have said to his colleagues just before the present war, "A cannon has no eyes." A gunner serving his cannon now gets the range from an aeroplane and drops a shell in a group of the

enemy five miles away. The chances are even that in this group the man of genius, the well groomed athlete of twenty, the mentally and physically fit will be killed as often as the stupid dolt who has barely passed the requirements for admission to the army. The poison gases injure all alike. Life in the trenches is responsible for serious mental as well as bodily harm in this long distance impersonal warfare of machinery and chemistry.

The bravest are placed in the front to lead the desperate charges and the rapid fire machine guns mow them down, the man who turns the handle of the gun having, perhaps, the minimum of fitness. The youngest men sustain the heaviest loss—those who have not yet become fathers,—while the older men, those over forty-five years of age, who have already raised as many children as they are likely to contribute to the state, are among the reserves, manning fortresses and coast defences and therefore exposed to no special danger. Thus the race must be propagated by the old men or by the physically or mentally unfit. Apparently at the present time war is national suicide.

It has been estimated that, if the European War lasts through next winter, France will have lost at least a million men either killed or so badly mutilated that they may be counted out of the history of the race, this million being made up of the very flower of the nation on the male side. In Germany and in Russia the same process is going on, on an even larger scale. England is raising an immense volunteer army and probably has at present about two and a half million men under arms. Although they are volunteers, the system of conscription in vogue in other countries not having been adopted in that country as yet, the army is made up of the best physical and moral force of the nation. It has been computed that of the 120,000 who fought at Ypres in October, comparatively few are left today to serve in the ranks. England has lost most heavily in the men of the upper and upper middle classes, who responded first to the call for troops. Many of the great families of the land have lost all of their male heirs and the English gentleman bids fair to become extinct.

Other factors to be kept in mind when considering the effects of war on the future of a people are the large numbers of illegitimate children that have been born in the immediate

vicinity of the military training camps; the inability of the soldier, because of his calling, to support a family, thus diminishing the birth-rate; and the known prevalence of syphilis and venereal diseases in armies.

W. L. B.

work is more accurate, thereby saving the management much of the cost of inspection. It is hardly necessary to add that the employees take kindly to this system and are on the best of terms with their employers.

PSYCHOLOGICAL SELECTION OF WORKMEN.

MUCH of the reproach which has been cast upon psychologists because of the apparent aloofness of their science from the affairs of every-day life is in a fair way to be obviated. When we find the ordinary psychologic laboratory tests applied daily in a large factory with a resultant increased efficiency of its employees, we are justified in optimism in regard to the practical future of psychology.

The average efficiency expert concerns himself with how the workman does his work, such problems as waste motion, and unnecessary duplication of effort; but the manager of a certain large manufacturing corporation believes in studying the personal equation, the capabilities and adaptabilities of the workman himself. He applies the routine laboratory tests for quickness of perception, degree of attention, and capacity for retention, to the applicant for employment, and determines first whether or not he shall be employed and, second, what work will suit him best. The results obtained have been amazing. The daily capacity of the men loading pig-iron on cars has increased from twelve and one-half to forty-seven and one-half tons per man, and at the same time their pay was increased 60%, and they were allowed time for rest.

Even more striking than these results are those obtained in the case of the girl employees who examine steel ball bearings and pick out the defective ones. To secure the girls best fitted for this work the manager made use of a simple psychological test. He employed those girls who were quickest to recognize a letter shown for an instant. Having selected the most suitable ones, he shortened their working day by two hours, gave them a Saturday half-holiday, four recesses during the day for recreation and even allowed those who needed it to take two days off at the time of their monthly period. As a result he has 35 girls doing the work 120 did before, they get twice as much wages and their

VACCINATION AND TETANUS.

THERE has been some tendency recently, in certain quarters at least, to suspect vaccination virus of being at times a source of tetanus infection, owing to the wide publicity which has been given to several cases of tetanus following vaccination. The anti-vaccinationists have, of course, made much capital of these occurrences, but they will find little comfort in some observations published by Dr. John F. Anderson, Director of the Hygienic Laboratory, United States Public Health Service, in the *Public Health Reports* for July 16. He has conducted researches for the past eleven years to determine what relation, if any, existed between vaccination and the cases of tetanus which now and then followed it.

Not to detail all his experiments, he failed to produce tetanus in monkeys and guinea-pigs, animals subject both to tetanus and vaccinia, even by vaccinating them with virus laden with tetanus germs. He examined enough virus to vaccinate two million individuals and failed to find any tetanus germs, although the methods used were demonstrated to have been always effective where the bacillus was known to be present. Moreover, the virus examined was later put on the market and cases of tetanus were reported following the use of some of it.

Dr. Anderson calculates that during this eleven-year period about 31,942,000 vaccinations were done and only forty-one cases of tetanus were reported, which in itself would be almost enough to brand them as coincidences. In the army and navy there were about 585,000 vaccinations performed from 1904 to 1913 with not a case of tetanus.

Dr. Anderson concludes, from his approaches to the subject from the above varying angles, that tetanus never occurs in vaccination proper and as a result of bacilli in the virus, but only by contamination of the vaccination wound, such as may occur in any wound not cared for properly.

TRICHINIASIS.

THE Health Department of the city of New York has called attention to an alleged increase in the number of cases of trichiniasis in that city, and while the disease is one that is not called for notification by the Sanitary Code, the department would welcome voluntary reports from physicians.

This disease may exist to greater extent than has been recognized, as the common use of uncooked meats increases with the growth of the population. The statement has been made that no examination of a carcass can make sure that the animal was not infected. Doubtless, some human cases are never recognized. Although the symptoms of muscle pain, followed by edema of the face, are well known, mild cases may easily be classed as rheumatism or typhoid before the microscopic search for eosinophilia and cysts is made.

Physicians know that the severity of the disease depends on the number of unkilld embryos swallowed. Those liberated from the meat by the digestive processes reach the adult stage in about three days, and within ten days have produced hundreds of young, some of which pass out with the feces, others penetrate the intestinal walls and pass into the muscles. The adults may survive as long as two months in the intestine and turn out many broods. These can be counted as the sole source of supply, as the young never develops to adult life in the intestine before passing through the muscle cyst stage.

A considerable quantity of raw pork and beef is eaten in this country, in mixtures called "salame," "cervelat," "roulade," and raw smoked ham products. It would be well for consumers of these delicacies to know the danger and to learn "that two per cent. of all hogs are trichinous." The bulletin also quotes Dr. Osler as stating that "post-mortem statistics show that from one-half to two per cent. of all bodies contain trichinae."

MEDICAL NOTES.

NEW YORK DEATH RATE LOW.—During the week ending August 7, 1915, there were 1451 deaths as compared with 1314 for the corresponding week of last year. The respective rates were 13.04 and 12.28. Making allowance for increase in population of 1915 over 1914,

there was still an increase of 85 deaths. While there were no deaths directly from insolation, the deaths from diarrheal diseases were more numerous during the past week than during the corresponding week of last year. Heart disease, pulmonary tuberculosis and violence showed an increase. Considering, however, the fact that the temperature during the past week was the most unbearable that the city has experienced in a great many years, it is a source of gratification that the number of deaths was kept within the figures above given.

The rate for the first 32 weeks of 1915 was 13.78, as compared with 14.57 for the corresponding period of 1914.

METHODS OF FIRST AID TREATMENT.—During the past year a special committee of U. S. army surgeons in Washington have been engaged in an investigation of the problems of first-aid measures and material, improved methods of transportation of wounded and more efficient fixation of injured extremities, as applied to military surgery.

The necessity for this investigation was furnished by the deplorable lack of uniformity in the methods used, since these have been found to vary not only in the armies of the different nations now at war, but also in the different departments of our army and navy at home.

Careful testing of first-aid packages, dressings, drugs, splints and other material employed in the administration of first aid, as well as the study of the best methods of employing them, is expected to lead to the standardization of first-aid material and methods. These will be incorporated in a First-Aid Manual to take the place of everything that has been arbitrary and confusing in the past.

It has been suggested that the results of this investigation should be just as useful and far-reaching when applied to the demands of accident surgery in industrial pursuits, as to military surgery, since selection of the best and its standardization must needs lead to economy and efficiency.

A number of surgeons engaged in the practice of accident surgery in the service of large industrial enterprises, whose opinion on this aspect of the problem has been sought, were so impressed with the mutual benefits to be derived from supplementing the investigations of the army and public health service officers, with the wealth of practical experience of the corporation surgeon, that a movement was set on foot for a joint conference of the different services and with the object of crystalizing ideas and more clearly defining the problems involved.

This meeting was held on Monday and Tuesday of this week, August 23 and 24, at the New Willard Hotel in Washington, D. C.

RELEASE OF QUARANTINE IN MARYLAND.—Report from Washington, D. C., states that on

Aug. 16 the federal quarantine against foot and mouth disease was raised throughout Maryland.

LONDON DEATH RATES IN JUNE.—Statistics recently published show that the total death rate of London in June, 1915, was only 12.2 per 1000 inhabitants living. Among the several districts and boroughs, the highest rate was 18.3 in Shoreditch, a crowded eastern slum, and the lowest was 8.3 in Wandsworth, a populous suburb on the south.

A WELSH MEDICAL SCHOOL.—It is announced that a medical school, open to women as well as men, is to be established in conjunction with the University of Wales, probably at Cardiff. Hitherto there has been no Welsh medical school, and students from that country have gone chiefly to Edinburgh, Glasgow, Aberdeen, St. Andrews, or Manchester.

AMENDMENT TO THE WISCONSIN EUGENIC LAW.—It is announced that, owing to the notable decline in marriages in Wisconsin, since the enforcement of the so-called eugenic law, noted in various issues of the JOURNAL, the law has been amended to make its requirements less rigid, and permitting physicians greater liberty in granting certificates.

EDUCATIONAL WORK FOR THE PREVENTION OF BLINDNESS.—The National Committee for the Prevention of Blindness has recently issued a circular, describing what women's clubs and nursing organizations can do to prevent blindness. It was written in response to frequent requests from nurses and club women for guidance in initiating or continuing prevention of blindness work. It describes the method of treatment of ophthalmia neonatorum, points out the dangers of midwives, discusses the adequate care of eyesight of school-children, industrial accidents and wood alcohol, and follows each subject with suggestions for the proper regulation and supervision of these dangers on the part of the community.

MILITARY CAMP FOR MEDICAL OFFICERS.—There is held during August in Tobyhanna, Penn., a military camp for the training of United States medical officers of the organized militia and doctors of the United States army medical reserve corps, the latter of which number about 1500 physicians and surgeons. The course lasts seven days for each class and there are six classes.

"The chief duty of the medical department in campaign is to relieve the fighting forces from the burden of caring for the sick and wounded at the front. This means that transportation of immense numbers of disabled men must be accomplished by the medical department.

"Viewed in this light, it is readily seen that medical department administration in the field

requires a large measure of military talent in troop leading, and that unless the division surgeon can have the services of a real military force his efforts will result in chaos.

"It has been found in all armies that the wounded have a better chance of recovery if their treatment is postponed until their arrival at the base, where proper facilities can be provided for their care. The military surgeon at the front is most successful when he refrains from practising medicine and surgery and devotes his entire energy to rendering first aid and arranging for prompt evacuation to the rear of all of his charge.

"A surgeon possesses surgical judgment and is able to separate those who can from those who cannot be transported, and he is able to give satisfactory first aid. In all active particulars his duty on the firing line could be performed by a line officer. This explains the military axiom that a line officer would make a better military surgeon at the front than any civilian surgeon who has not received a military training. The definition of a military surgeon is a 'soldier who has specialized in surgery, sanitation and medicine.'

"The last few weeks of the camp at Tobyhanna will be given over to the instruction of militiamen who have specialized as field hospital and ambulance company commanders, but during the first weeks of the camp only general instruction has been given."

EUROPEAN WAR NOTES.

SURGICAL DRESSINGS FOR THE WAR.—A recent report of the surgical dressings committee of the New England branch of the National Civic Federation states that during the past year this organization has prepared and sent to Europe over 300,000 dressings for the wounded. These have been variously distributed as follows:—

"We have sent our dressings to the Princess Joachim Murat's hospital to Mrs. George Howland for a hospital at Montreuil, to the Baron de Luze Hospital, Benevole, to the American Women's War Relief Hospital at Paignton, to the American Clearing House for general distribution, to the French Wounded Emergency Fund, to the Belgian Hospital at La Panne, for Serbian sanitary relief, and for the St. John's Ambulance Association. This last depot, through which we have constantly sent supplies through the agency of Mrs. Clipston-Sturgis, we have found to be most business-like, reaching the hospitals in France sooner than by any other agency except that of the American Clearing House. Richard Norton was allowed to requisition our supplies from the St. John's depot and to have them forwarded direct to his ambulance corps in France. He wrote expressing the greatest delight that at a crisis when supplies were failing the French army, he was able to give them dressings which had been made here in Boston by your committee. It was

after this episode that we had very complimentary letters from the surgeon-general of the second French army, and from Lord Stanmore of the St. John's Association."

ITALIAN WAR RELIEF.—The president of the New England Italian War Relief Committee has issued the following appeal for funds:—

"This committee has been formed to aid in relieving the distress which the European War brings to non-combatant Italians. Our immediate purpose is to help the women and children left destitute by the call of their wage-earning husbands and fathers to the war. Some of these are families of reservists summoned to Italy, and live in this country; a much larger number are in Italy itself. The inevitable casualties on the field and in the hospitals add daily to the list of those left without support.

"In our work we are promised the assistance of the Italian ambassador at Washington, Count Vincenzo Macchi di Cellere, who gives the movement his cordial approval and consents to oversee the distribution of the funds. As our means permit, we shall extend the field of relief, always keeping in view the most pressing needs.

"We appeal in the name of humanity, which calls on everyone to succor especially the innocent victims of war. We believe also that many Americans, who acknowledge their debt to Italy for her service to civilization, and for the pleasure and inspiration which they have personally received from her, will welcome this means of expressing their gratitude.

"Messrs. Lee, Higginson and Company, 44 State Street, Boston, have kindly consented to act as treasurers of the fund, and to acknowledge through the newspapers the subscriptions received. Checks should be sent to them, payable to the order of the New England Italian War Relief Fund."

WAR RELIEF FUNDS.—On Aug. 16 the totals of the principal New England relief funds for the European War reached the following amounts:—

Belgian Fund	\$267,043.12
Italian Fund	1,579.10

BOSTON AND NEW ENGLAND.

BOSTON MILK AND BABY HYGIENE ASSOCIATION.—In a recent statement to the daily press, Mr. George R. Bedinger, director of the Boston Milk and Baby Hygiene Association, comments as follows on the work of the Association this season and during the past four years:—

"The managers and officials of this association are peculiarly gratified at the steady and rapid improvement of Boston as a safe place for babies. Four years ago this city ranked seventh among the ten largest cities in its record for the reduction of infant mortality, as measured by the baby death rate. Last year it had

risen to second place, tied with St. Louis, New York being in the lead. For the first half of this year it has a lower death rate than New York City. The number of babies cared for by the association has steadily increased, the number four years ago being 2827; in 1912, 3026; in 1913, 3421; in 1914, 4097; and for the first seven months of this year 3438. Indications certainly point to an infant death rate for 1915 below 100 per 1000 births, which, if attained, will be a new record for our city."

NEW ENGLAND CANCER DEATH RATES.—In the registration area of the United States the cancer death rate is 78.9 per 100,000 of population, but in New England the rate is considerably higher. In Connecticut it is 85.1; in Rhode Island, 93.3; in Massachusetts, 101.4; in New Hampshire, 104.4; in Maine, 107.5; and in Vermont, 111.7. Probably two factors are concerned in this phenomenon: first, the relatively high age distribution; second, the greater predominance of Yankee stock in the New England states. In Kentucky the rate is only 48 per 100,000.

THE BOARD OF HEALTH, NEWPORT, R. I., was organized on January 30, 1914, with Dr. Rufus E. Darrah president and Dr. George D. Ramsay secretary. During the year thirteen regular and eighteen special meetings have been held. The first annual report of the Board gives the following facts: The number of deaths from all causes was 333, which gives an annual death rate of .1135. The cause of the greatest number of deaths was organic disease of the heart, with cerebral hemorrhage coming second. No deaths were reported from typhoid fever for the year. There occurred but seven cases, two of the patients being taken from vessels in the harbor. Four deaths occurred from whooping cough. One case of pellagra, resulting in death, the first ever known to occur in the city, was reported.

TYPHOID AT GRAFTON STATE HOSPITAL.—In the monthly bulletin of the Massachusetts State Department of Health for June, 1915, is published a report of a recent typhoid outbreak in the Grafton State Insane Hospital:—

"This institution consists of what was formerly called the Worcester Insane Hospital, Summer Street, Worcester, as well as four colonies situated in North Grafton.

"In Worcester at the time of the outbreak there were 638 patients and 169 employees, while at North Grafton there were 831 patients and 200 employees, making a total of 1838 for the entire institution.

"On May 8, 1 positive typhoid reaction was obtained from Worcester and 2 from Grafton, and 1 each from both places on May 15. The Worcester cases were from two different female wards, fed from a common kitchen, and no cases or suspicious cases were found in the male wards or among the employees.

"The 3 cases in North Grafton were from three different female wards, fed in three different dining rooms, served from a common kitchen. These three dining rooms and kitchen are in the Pine Service Building, where 330 patients and 40 nurses take their meals. Very little of the nurses' food is handled by the patients, as most of this is done by the cook and her assistant, while most of the patients' food is handled and served by the patients themselves. In all departments at North Grafton milk is freely served and used three times a day. No cases or suspicious cases were noted on the male ward or among the employees at North Grafton.

"No history of recent illness, malaise or indisposition of any kind was obtained from those handling the milk or other food.

"The milk supply of the institution was obtained from B. and from N. of North Grafton, as well as about 200 quarts daily produced on the two farms connected with the colony in North Grafton. All of the milk, however, was not mixed; none of N.'s milk went to North Grafton; none of the milk from Colony 1 went to Worcester; and none of B.'s milk was used in Grafton. The milk from the O. farm in North Grafton was the only portion of the supply used at both Grafton and Worcester. The milk was not bottled, but was delivered by B. in his own cans, which were handled, collected and washed by his men. The milk from N. is collected in cans furnished by the institution. These cans, as well as those used at the two farms in Grafton, are furnished by the institution and are washed with steam and warm water at Grafton, but not actually sterilized. Since the beginning of the outbreak, however, satisfactory additional precautions have been taken.

"There was no history of typhoid or any other suspicious indisposition on the B. and N. supplies.

"As soon as the first cases appeared, all suspected 'contacts' were vaccinated, and later, all employees; and when it was suggested that every one in the institution be vaccinated, arrangements were made forthwith to carry out this suggestion at the rate of about 100 cases a day. To date (June 14) all employees at Grafton and Worcester have received their third treatment, and all patients, with a very few exceptions, have received their second, so that inside of ten days every one in the entire institution will have been vaccinated."

Obituary.

CHARLES WILLIAM PRENTISS, Ph.D.

DR. CHARLES WILLIAM PRENTISS, who died of duodenal ulcer on June 12, 1915, at Chicago,

was born in Washington, D. C., on August 14, 1874. His youth was spent at Middlebury, Vt., and he graduated from Middlebury College in 1896. Later he studied in the department of zoölogy at Harvard University, from which he received the degree of Ph.D. in 1900. For a year he taught as assistant in anatomy at the Harvard Medical School and then devoted two years to travel and study in Europe, chiefly at Freiburg, Naples and Strassburg.

Returning to the United States in 1903, Dr. Prentiss held teaching appointments in the zoölogical departments of Western Reserve University and of the University of Washington at Seattle. In 1909 he was appointed assistant professor of anatomy at the Northwestern University Medical School, and in 1913 became professor of microscopic anatomy in that institution, a position which he held until the time of his death.

Dr. Prentiss was a member of the Association of Anatomists, the Society of Naturalists and the Society of Zoölogists. He was a prolific writer on topics in anatomy and zoölogy, and published many papers presenting the results of his own investigations in these fields of research. In January, 1915, was published his text-book of embryology, a work which summed up the experience of his professional and scientific career and which was reviewed in the issue of the JOURNAL for April 29, 1915 (Vol. clxxii No. 17).

In an obituary notice of Dr. Prentiss by S. Walter Ransom in the issue of *Science* for Aug 6, is the following estimate of his character and professional ability:—

"Professor Prentiss's scientific work was characterized by a scrupulous attention to detail and by the perfection of his technical methods. He handled with great success and on difficult material the most delicate of neurological methods—the methylene blue stain. His dexterity was shown again in remarkable dissections of embryos, drawings from which appeared in his book. He brought to all his work an unusually clear mind and a keen insight into fundamental problems.

"Retiecent, almost shy, by nature, and prevented by the condition of his health from often joining his colleagues at the regular Christmas meetings, Dr. Prentiss was intimately known to only a chosen few. To them he was endeared by reason of his unflinching good humor, generous motives and loyalty to high ideals and to his friends. Admired and respected by all conscientious students and loved by those who came into close contact with him, he helped greatly toward the establishment of high standards of scholarship and manhood in the student body."

Miscellany.

A GRAECO-EGYPTIAN OBSTETRIC INSCRIPTION.

In a recent bulletin of the Archeological Society of Alexandria, Professor G. Arvanitakis publishes the text of a Greek inscription lately discovered in Egypt, relating to a patient, Herois, who died in childbed, and the obstetric circumstances associated with her death. The *Lancet* presents the following translation of the inscription and comment upon it:—

“Who is the dead one? Herois. How and where? Having a tumor ($\delta\gamma\chi\omicron\varsigma$) in the stomach. And, notwithstanding that we placed weight (in the form) of Isis; the mother was lost very quickly, and then the child also. What was her age? Eighteen. So Herois was in the power of her age. Oh, the unfortunate one. May Isis render her ashes light and grant her sweet water.’ The story told in this record is one which, it is to be feared, was of frequent occurrence about the commencement of our era. Herois’s first accouchement had arrived, and the doctor, or midwife, acting as attendant, finding the delivery delayed, proceeded by mechanical means to accelerate matters. He took a weight made in the form of a figure of Isis, a residing deity on such occasions, and either placed it upon the mother’s abdomen as, as is more probable, attached it by a cord to the already projecting part of the infant. In this case the mother would have been placed in a sitting posture, resting upon two stools, or standing erect. The erroneous practice in the case referred to produced the delivery of the child, doubtless injured, for it died shortly after the mother. The word translated tumor is $\delta\gamma\chi\omicron\varsigma$, which Galen uses solely with that meaning.”

Celtic nard. In severe cases, try the vinegar of squills. Holding the breath is of use. Aetius gave emetics, then narcotics, and finally applied a cupping instrument with great heat to the breast, belly and back. Alexander began with bleeding when the hiccup was connected with inflammation of the stomach or liver. The author of the ‘Euporista’ put the patient’s feet in hot water, gave him tepid drinks, and applied hot fomentations to the belly. We now quote from Pliny the elder, translated by Philemon Holland: ‘But, against the Hocquet or Yex there is a notable medicine made with it (colewort), together with coriander, dill, honey, pepper and vinegar. If the pitch of the stomach be anointed therewith the patient shall evidently perceive that it will dissolve the wind and puffing ventosities therein.’

“Pliny gives 15 or 16 remedies. Garden mint, with the juice of a pomegranate, is one of them. And note this use of mint: ‘The juice of mint is excellent for to scour the pipes and clear the voice, being drunk a little before that a man is to strain himself either in the choir, or upon the stage, or at the bar.’ This shows why consumers of mint juleps are talkative.

“And now consult Mr. Topsell’s ‘History of Four-Footed Beasts’: ‘If that any man do get and put up the shoe of a horse being struck from his hoof as he travelth in his pace (which doth many times happen) it will be an excellent remedy for him against the sobbing in the stomach called the hicket.’

“Turning to that invaluable book of medicine, ‘A Thousand Notable Things of Sundrie Sortes,’ by Thomas Lupton (London, 1627), we find (Book IV. 82): ‘Stop both your ears with your fingers and the hickop will go away within a while after. Proved.’ Here is a quicker cure (Book VI. 4): ‘It is proved, and a secret: that if you give to them that have the hickop every morning three hours before meate one roote of greene Ginger, and immediately after drinking two draughts of Malmesey, you shall see that he will become cured. Emperici benedicti victorii.’”

ANCIENT REMEDIES FOR HICCUGH.

A RECENT article by Dr. John A. Wyeth of New York on hiccup and on the various remedies therefor led Mr. Philip Hale to extract from classic and medieval literature a number of such remedies whose efficacy was considered certain. He writes in part as follows upon this interesting subject:—

“The remedies are countless. The ancients, apparently ignored by Dr. Wyeth, recommended many. They knew that if you took the medicine composed of the three kinds of pepper and rank wine immediately afterwards, you would cure the hiccup. When emptiness of the stomach is a cause, sneezing will not put an end to the spasms. Paulus Aegineta advises in this instance use with wine, or nitre in honeyed water. Hartwort, carrot, cumin, ginger, calamint, or

BRITISH SURGEONS IN INDIA.

IN the issue of the *British Medical Journal* for May 25, 1907, appeared an article entitled “British Medicine in India,” in which was given an account of some of the physicians who played an important part in the establishment of the British Empire in India. Among these was Dr. Gabriel Boughton who, in 1645, obtained for the East India Company the concession which first gave it a secure footing in India. Another was Dr. William Hamilton, who in 1715 cured the Indian Emperor at Delhi of a malignant distemper, in gratitude for which the Great Mogul received favorably the British Embassy, of which Hamilton was a member.

Dr. John Zepheniah Holwell in the 18th century was chief surgeon of the Bengal presidency and afterwards was mayor of Calcutta. When the city was sacked in 1756 the governor fled and Dr. Holwell took command of the garrison and was one of the prisoners who survived the Black Hole. In 1760 Holwell succeeded Lord Clive as governor of Bengal.

Another memorable practitioner of Calcutta was Dr. Richard Cheese, who is commemorated by a monument in that city. In the issue of the *British Medical Journal* for June 12, 1915, is quoted the following epitaph from his tombstone. Dr. Cheese went to India in 1792 and died there in 1816.

Sacred to the Memory of the late

RICHARD CHEESE, Esq^{re},

Surgeon to the Hon^{ble} Bengal Company's
Establishment and Garrison Surgeon of
Fort William

Dedicated by Public Contribution

In token of the high and well merited Esteem of
the Community

For the Enlarged and Practical Philanthropy of
that Gentleman's character.

Perhaps never had the remains of a Christian in
India been followed to their tomb

With more heartfelt and Expressed Regret
Than were manifested by the Numerous Assem-
blage

Of all classes of the Society of the Place
Who attended the Funeral on the 15th Jan.,
1816.

He had long exercised his Professional Talent
With an Ability which did Honour to Him as a
Practitioner of Medicine.

And with a Munificence Worthy of the Religion
he professed.

If a change of Air, or Expensive Nutriment
were desirable

But could not be afforded from the Resources of
the Patient—

Mr. Cheese supplied the Means.

And when all Human Endeavours proved
Unavailing

His Purse was ever open to clothe and support
the destitute Mourners.

In the Society of His Equals

Such was also the cheerful benignity of his
Manners

That he was ever a Welcome Guest

Alike to the children and to the Heads of the
Family.

UNITED STATES NAVY MEDICAL CORPS.

At the preliminary examination beginning July 6, 1915, held in various cities of the United States, for examination of candidates for appointment as assistant surgeons in the Medical Reserve Corps of the Navy with a view to subsequent examination and appointment in the Medical Corps of the Navy after a course at the Naval Medical School, the following candidates were found physically and professionally qualified:

1. Virgil Hope Carson, M.D. (Medical College of Virginia); Interne, New York City Hospital.

2. Elphege Alfred Gendreau, M.D. (Georgetown University Medical School); Interne, Providence Hospital, Washington, D. C.

3. Francis DeArmond Gibbs, M.D. (Georgetown University Medical School); Interne, Georgetown University Hospital and Children's Hospital, Washington, D. C.

4. John Harper, M.D. (Medico-Chirurgical College of Philadelphia, Pa.); Interne, Medico-Chirurgical College of Philadelphia.

5. Forrest Martin Harrison, M.D. (George Washington University); Interne, Government Hospital for the Insane, Washington, D. C.

6. Richard Hagan Miller, M.D. (Jefferson Medical College); Ph.B., 1907 (Brown University), A.M., 1909 (Brown University); Interne, Rhode Island Hospital, Providence, R. I.

7. John Paul Owen, M.D. (St. Louis University); Interne, Hospital and Health Board of Kansas City, Mo.

8. John Floyd Pruett, M.D. (Leland-Stanford University); A.B., 1909 (Leland-Stanford University); Interne, Lane Hospital, San Francisco, Cal.

9. William Jehiel Rogers, M.D. (Western Reserve University); A.B., 1911 (Adelbert College, Western Reserve University); Interne, St. Vincent's Charity Hospital.

10. George Patrick Shields, M.D. (University of Pennsylvania); Interne, Methodist Episcopal Hospital and St. Agnes Hospital, Philadelphia, Pa.

11. George Washington Taylor, M.D. (Tulane University); B.S., 1909, M.S., 1910 (Alabama Polytechnic Institute); Interne, Illinois Central R. R. Co. Hospital, New Orleans, La.

12. Russell John Trout, M.D. (New York University and Bellevue Hospital Medical School); Interne, Bellevue Hospital.

13. George Boyd Tyler, M.D. (Medical College of Virginia); Interne, Marine Hospital, Chicago, Ill.

14. Walter Alfred Vogelsang, M.D. (University of Tennessee); Interne Contagious Disease Hospital New York; Ernest Wever Hospital, Buffalo, N. Y., and Tuberculosis Preventorium for Children, Farmingdale, N. Y.

15. Grover Cleveland Wilson, M.D. (University of Virginia).

16. Charles Henry Weber, M.D. (Marquette University); B.S. (Marquette University); Interne, National Military Home, Ind.

Address.

SCOPE OF PUBLIC HEALTH SERVICE.*

BY WM. C. HANSON, M.D., BELMONT, MASS.,

Formerly with the Massachusetts State Board of Health.

THE scope of public health service has become exceedingly broad. All the fields of the medical and related sciences form the foundation of public health work.

The purpose of public health work is to protect and promote the health of the citizens to the end that their usefulness may be increased.

The distinction between public health and private health is arbitrary and unimportant, although some diseases are better illustrations than others of the necessity for a public health service.

Lemuel Shattuck, a very intelligent layman, proposed to the Massachusetts Legislature of 1850 "An Act for the Promotion of Public and Personal Health." In one of the most remarkable public health documents ever written, now more than half a century ago, Shattuck said that "the great object of sanitary science was to teach people the causes of disease,—how to remove or avoid these causes,—how to prevent disease,—how to live without being sick,—how to increase the vital force,—how to avoid premature decay." "One of the most useful reforms," he said, "which could be introduced

into the present constitution of society would be, that the advice of the physician should be sought for and paid for while in health, to keep the patient well; and not, as now, while in sickness, to cure disease, which might in most cases have been avoided or prevented." Shattuck was many years too early for his time, but we are fast following the lines of action that he described with such remarkable foresight.

No branch of preventive medicine has excited greater interest of late years than the study of the effects of occupation on health and length of life. Massachusetts was the first state to begin the scientific study of the physical effects of child labor in America. Owen R. Lovejoy, secretary of the National Child Labor Committee, recognized this fact when in 1912 at the International Congress of Hygiene and Demography he said: "This public service has been to some extent developed in Massachusetts, and creditable work has been done by the State Board of Health. In other states but slight beginnings can be recorded." At this same Congress, the president, Dr. H. P. Walcott, for 25 years president of the Massachusetts Board of Health, said in regard to the prevention of occupational diseases: "We should now bend all our efforts to a course of determined and persistent administration in the hands of instructed and public-spirited officers acting with all the great powers conferred by existing statutes."

It may not be amiss in this connection, in view of the importance of the subject for the protection of the community, to state that at this International Congress the Massachusetts Board of Health was awarded a diploma for superior merit

* Read as the Annual Oration for the Middlesex South District, Massachusetts Medical Society, New American House, Boston, April 1, 1915.

for its exhibit on the hygiene of occupations. It was the only award made on the subject to any state or municipal exhibitors. The jury, appointed by the executive committee of the congress, consisted of nine disinterested persons occupying prominent public positions, the chairman of which was Major Russell of the United States Army Medical School.

Less than eight years ago the Massachusetts Board of Health took on the scope of an investigation of work and conditions dangerous or injurious to the health of children in factories. The investigation was made by physicians. They were interested in determining the facts relating to the work and health of the children, and their efforts and results undoubtedly accomplished much good. The investigations were begun without any definite idea of paying attention to more than the sanitary conditions in factories generally, but we soon realized that the best protection of the industrial workers was to look after the children and youths in gainful occupations. There was nothing flaring about the work, which by actual growth up to 1912 directed itself towards securing the greatest possible protection for the young person, who we realized had a longer life before him than the adult and who we felt ought to be insured the best possible chances of making the most of himself without any more risk from contagion of any kind or of avoidable occupational diseases or unhygienic conditions which encouraged diseases or disease tendencies than could be avoided.

As the result of the investigations, a considerable variety of occupations were practically closed to young persons under eighteen years of age and the occupations of many children changed. Many thousands of children were examined physically and conditions of ill health pointed out to their parents or guardians.

It was impossible, however, to obtain without the coöperation and assistance of women well trained in investigating the habits and interests of young workers the really practical results that might otherwise have been obtained. This is true because the services of public health nurses and social workers are necessary for the proper education and care of young persons in industry just as they are necessary in aiding progress in dispensary work by going into the homes of the sick.

The especial usefulness of women in this capacity is to follow the children along and help them live healthier and more useful lives. It will still be the function of the health physicians, however, to correlate the injurious influences of the occupation, of the home and of the habits of the individual. For these physicians are the persons who are most experienced in preventive medicine, and as public health officials are best able to judge as to the various effects of occupation or of living conditions on health.

Recently Hayhurst, for the Ohio State Board of Health, has carefully investigated the subject of occupational health-hazards in that state. He

has defined a certain number of health-hazards which he believes to be responsible for a large percentage of preventable sickness and mortality, *e.g.* tuberculosis, cancer, rheumatism, circulatory diseases, Bright's disease, and skin diseases. He believes that deaths occurring under seventy years of age from circulatory or heart diseases should be considered preventable.

"In Ohio in 1912 over one-sixth of all deaths were due to circulatory diseases and one-eighth of all deaths to organic heart disease alone. As a cause of death tuberculosis has been almost doubly outstripped by these three chronic degenerative diseases, 58% of which have occurred before 70 years of age, and 20% of which have occurred before 50 years of age." The total number of cases of positive occupational diseases and disabilities discovered by the Ohio investigation this last year, was more than 1200.

The health department of the city of New York has within the last two weeks added to its duties the one of studying the effects of occupation on health. A division of Preventable Diseases was established, including a central occupational disease clinic and an industrial hygienic educational division. During the interval mentioned the clinical material has exceeded that of the tuberculosis clinic. It is expected that work conducted along the lines indicated will be a potent factor in the reduction of mortality and morbidity in the city.

Among the unofficial organizations interested in the prevention of occupational diseases is the American Public Health Association, which at its last meeting voted to appoint a special committee to consider and report on the subject.

What is really happening, therefore, is the through educational reforms the public is beginning to see what a few men like Lemuel Shattuck saw a great many years ago. In Shattuck's time but few persons were educated in sanitary science; now there are many persons capable of giving good sanitary advice. Sanitary professorships are being established in all of our colleges and medical schools, and the science of preserving health and preventing diseases is taught as one of the most important subjects.

Today in our community thousands of persons who are well are seeking advice as to how to keep well. Good health is being generally recognized as lying at the foundation of success for both the individual and the community.

Persons as a rule, however, are not yet ready to pay for advice as to how to keep well, except through taxation by the agencies of government.

The United States Government, state, city and some town agencies are distributing literature free of cost to the individual on any phase of preservation of health. Some of the most common subjects of the day, for one reason or another, are: the prevention of occupational diseases; the control of the notifiable communicable diseases; the study of the prevalence and control of venereal diseases; pneumonia; cancer; circulatory and organic heart diseases; Bright's dis-

ease; diabetes; the problem of infant mortality and child hygiene; school hygiene and the examination of school children; housing conditions; rural sanitation; and the prevention of the pollution of our water supplies.

To show one way and the extent to which some states are going in educating the inhabitants in the preservation of health, one state, at an expense of a number of thousand of dollars, issues a Mother's Baby Book bound in cloth. The book is sent by the Governor with an autographed letter to each mother after the birth of her first baby. The object of the book is to give simple and plain instructions concerning pregnancy, childbirth and the care of babies. It is intended to supplement and aid the physician, and not to prescribe medical treatment. Another object of the book is to bring about a more complete birth registration which, in turn, permits a more complete record of infant mortality.

Public health service deals with law. The rights of property and persons must be guarded. On the other hand, no person shall so use his property, or allow it to be used, as to be dangerous to the public health. Furthermore, no person shall perform any act or cause any act to be performed which shall cause or spread dangerous diseases, or which shall otherwise endanger the public health. And, finally, every person should do or cause to be done all things reasonably necessary to prevent dangerous diseases, or the spread thereof, and to protect and promote the public health.

Reasonableness of action is important. Administrative authorities, local and state, must use due caution in passing ordinances, rules and regulations.

A health board to be successful must consider and weigh carefully the reasonableness of all its acts and the omission of acts. The reasonableness of acts or the omission of acts must always be based upon facts. They should never rest upon the work of any one man or class of men. The health authority of our local community is, with rare exception, in our Commonwealth the most powerful, final authority. A local board of health actively engaged and using all its powers is comparable to a court in continuous session.

The interpretation of laws enacted many years ago and their adaptation to existing conditions is often perplexing. And yet, law must be interpreted not only in the light of the knowledge existing at the time of its enactment, but in accordance with present day enlightenment, in keeping with advancing civilization. Measures which would have been sufficient and reasonable a few years ago, owing to lack of knowledge at that time, might today in the light of existing knowledge be declared unreasonable.

In order to prevent or suppress any communicable disease, we must have a knowledge of its mode of transmission. This is essential, whether for personal prophylaxis or in the general warfare against infection.

The most common communicable diseases that

show gradually diminishing death rates in our Commonwealth are: tuberculosis, typhoid fever and diphtheria. The causes for the diminishing death rate from these diseases are somewhat complex, although it is fair to give exceptional credit to (a) the use of bacteriological and research laboratory knowledge, (b) the improvement in the purity of our water supplies and in the proper removal of sewage, and (c) the combined efforts of the laity, the medical profession and sanitarians in the practical study of good hygiene and the prevention of disease.

TUBERCULOSIS.

Lemuel Shattuck in 1849 stated that if tuberculosis was "ever to be eradicated or ameliorated, it can be done only by preventive means and not by cure." Dr. Fisher of Boston, an eminent professional man of Shattuck's time, said that "preventive means, when known and fully appreciated by the community, will be adopted, to a greater or less extent, and by their adoption a vast amount of human suffering and human life will be saved." This was a true prophecy.

Hiram F. Mills, for thirty years with the State Board of Health, made in 1913 an exhaustive study of what has been accomplished in the past in the suppression of pulmonary tuberculosis, the present condition in the state of Massachusetts, and the most effective methods of acting and coöperating with all the forces engaged in the suppression of this disease. Mr. Mills' plan of campaign for the suppression of tuberculosis goes to the root of the matter by removing all conditions which cause its spread and inspiring hope in sanitary measures that will prevent its recurrence. The following statistical information is found in his report:—

"Forty years ago the death rate from tuberculosis in Massachusetts was three times as great as it is now; today it has been reduced one-half in the past twenty years.

"There is no other state in the union, in which records have been kept, where the reduction of the death rate from tuberculosis has been as great as in Massachusetts.

"Furthermore, no other country in the world has done such effective work and accomplished so much in decreasing the number of deaths from tuberculosis per 100,000 of population as has the Commonwealth of Massachusetts."

In the further suppression of this disease the work of district nurses, public health nurses and social workers under the supervision of both state and local health authorities is strongly recommended in connection with the establishment and maintenance of tuberculosis hospitals and dispensaries.

TYPHOID FEVER.

About two years ago, at the suggestion of the reader, a special committee of state health officers, acting under his supervision, in-

vestigated the prevalence of typhoid fever in Massachusetts to determine what aggressive work might be inaugurated in our Commonwealth in order to reduce the typhoid mortality rate. It was found, from figures compiled by A. J. McLaughlin in the Public Health Reports, that the typhoid mortality rate showing for this country, as compared with the rate for certain cities of northern Europe, was far from flattering. The registration area of the United States had an average mortality rate for the years 1901-1909, inclusive, of more than six times the 1910 rate for the European cities. Many European localities had reduced the average mortality from typhoid to about 4 per 100,000. The result was equally unfavorable in making a comparison with the cities of this country. Of the 50 registration cities of the United States, with a population of 100,000 or over, in 1910, but 4 had a typhoid mortality rate of 9.5 per 100,000 or less.

The Massachusetts rate for the years 1908-10, the lowest typhoid mortality rate for 25 years, was nearly three and a half times higher than the low average European rate mentioned. While, however, there are and have been in these northern European countries fewer deaths from typhoid fever per 1000 inhabitants than in Massachusetts, the death-rates in Massachusetts have decreased more than in any one of those countries, and have decreased twice as much as the average of them all.

The committee found many difficulties having to do with the agencies through which the infection is spread, and recommended state-wide legislation for bringing up to a proper standard the health work in those communities as yet not sufficiently active or organized. The proposed legislation, however, has not been forthcoming. They were of the opinion that carriers should be restrained from handling all food products whether in dairies, kitchens or dining rooms. They were also of the opinion that "the physician who does not report a case of continued fever as a probable typhoid as soon as he has eliminated other common causes, and who does not in such a case take appropriate precautions, must shoulder very serious responsibility to the community for any subsequent results in the community."

In the past twenty-five years, while the population of Massachusetts has increased 67%, the deaths per year have increased but 30% and the death rates have decreased from 19.83 to 15.42, or 4.41 per 1000 living.

In the twenty years previous to the organization of the late State Board of Health there had been but little permanent change in the death rate in the state. The average death rate in that period was 19.33 per 1000 and in the last five years of the period it was no less than the average.

In the first twenty years of the work of this board the death rate decreased from 19.83 per 1000 to 16.33, or there were at the end of this

period 16% fewer deaths per 1000 per year in the state than at the beginning.

Mr. Mills, commenting on the causes of the diminished death rate, laid the greatest stress upon the purification of our water supplies. "Other elements," he said, "have entered into the problems which have in the past been of less importance, but now that so much has been done in the improvement of water supplies, the other elements, especially the improvement of the milk supply, assume increased importance in decreasing the deaths now caused by typhoid fever and other germ diseases."

The year 1914 is noteworthy for considerable diminution in the typhoid death rate in the country. Forty-one cities had a lower rate than in 1913 and 17 a higher; 24 cities had a death rate under 10 in 1914 as compared with 19 in 1913.

The two Massachusetts cities, with a population of over 100,000 having a death rate under 5, were Worcester and Cambridge.

While there has been a steadily diminishing mortality from the disease in this state there is great need of the combined efforts of the health authorities and the public in bringing about its eradication.

DIPHTHERIA.

The discovery by Behring of the antitoxic power of the blood in animals treated with diphtheria toxin, and the successful attempts of Behring, Roux and others to produce antitoxin on a large scale, led Dr. H. P. Walcott, chairman of the State Board of Health, in 1894, to consider the advisability of establishing a laboratory for the production and free distribution, under state supervision, of this preventive and curative serum.

It is unnecessary to make more than a brief comment on the value of the prompt use of antitoxin for both its curative and preventive effect. The striking difference in the fatality from diphtheria, according to whether antitoxin is administered early or late in the disease, is well known.

In the pre-antitoxin period, for the years 1891-1894, the total fatality per cent. from diphtheria was 28.3; during the antitoxin period for the years 1895-1913 the total fatality per cent. was 10.8.

With the intelligent co-operation of the medical profession and the general public, the control and prevention of diphtheria is feasible. We must, however, have a knowledge of its prevalence and a better knowledge of its causation. We all know of the occasional outbreaks of positive bacteriological cases with no clinical symptoms, in other words, of the frequent finding of diphtheria bacilli in healthy throats. Whether such outbreaks are due to certain meteorological conditions, favoring the activity of the bacilli, seems to be a proper subject for further inquiry. Personally I am inclined to give-

weight to such a theory rather than believe that all cases result from direct case-to-case infection. I believe that every case of positive culture ought to be carefully investigated by a local health official and full records kept in the local office for ready access to the state health officers, so that the efforts of the bacteriologist and investigators may be combined in the interest of more accurate knowledge as to the control and prevention of this disease.

From 60% to 70% of all deaths from diphtheria occur in children under five years of age.

All cases of sore throat should be carefully watched, and, if more than one case occurs in a family, it should be regarded as suspicious.

Immunity in diphtheria is generally incomplete and of short duration. It lasts from a month to several years, varying greatly in different individuals, and being very brief in children.

Schick has recently proposed a simple clinical test for determining whether a person is more or less immune to diphtheria or whether a state of susceptibility exists. The most practical application of Schick's test, according to Kolmer and Moshage, "consists in applying the test as a preliminary measure to all persons who have been exposed to diphtheria, and immunizing only those who react positively." The test is "based on observations of von Behring that as little as one-hundredth of a unit of anti-toxin per cubic centimeter of our serum will protect a person against diphtheria."

Bundesen of the Chicago Health Department points out that the use of the Schick test "permits a great reduction in antitoxin bills, that much needless pain and annoyance of patients is avoided, and that the possibility of anaphylactic shock is greatly minimized."

MEASLES.

In the year 1910 over 11,000 American children died from measles. This number did not include the great number of children who died from broncho-pneumonia, a disease which is so frequently caused by measles. When it is considered that measles occur most often during the school period it will be seen that thousands of children are kept from school for weeks at a time on account of this disease. Leaving out of consideration the death and suffering caused by so many children stricken with measles, the economic loss is a most serious one.

Measles is now regarded as a preventable disease, yet in Massachusetts, in 1913, there occurred 315 deaths from this cause. In Illinois, during the year previous, there occurred from measles more than 650 deaths.

W. C. Rucker of the United States Public Health Service, commenting on the ravages caused by measles, said: "It is little less than criminal to permit children known to have measles to come in contact with well children. . . It is the duty of private citizens and

municipalities to take every known measure for the prevention of the spread of this disease."

The administrative control of measles remains one of the most baffling problems with which we have to deal.

SCARLET FEVER.

The essential features of the prevention of scarlet fever consist in isolation and practical disinfection. While scarlet fever is not so highly contagious a disease as measles, both diseases must be dealt with from a public health view point in practically the same way. Until more exact knowledge is obtained concerning the channels of entrance and exit of the virus and its mode of transmission, public health authorities will be more or less handicapped in its control. The period of isolation is necessarily more or less arbitrary in scarlet fever for we have no accurate way of determining just how long a child remains infective.

WHOOPIING COUGH.

Dr. John Lovett Morse in "A Plea for More Efficient Public Regulations Relative to the Control of This Most Serious and Fatal Disease," called attention to the fact that whooping cough is almost everywhere more fatal than scarlet fever and less fatal than diphtheria. In 1911 the reports from thirty states showed that 6251 died from whooping cough, 4323 from scarlet fever, and 9579 from diphtheria. During the same period in eleven states where 1216 children under five years of age died from whooping cough, 3860 children under five years of age died from bronchitis and broncho-pneumonia. While it was impossible to know in how many cases the bronchitis and broncho-pneumonia were secondary to whooping cough, Morse pointed out that they were undoubtedly due to it in a considerable proportion of them. He showed by statistics the lack of proper regulations relating to the isolation of children ill with measles and to the exclusion from school of other children in the family; of the scanty provisions for the hospital treatment of whooping cough in this country; and of the lack of a general rule as to the management of children with whooping cough in out-patient and dispensary clinics. Morse emphasized the need of making strenuous efforts to diminish the terrible mortality from this disease. He said (1) "It is fair to assume that the disease is transmitted by the secretions of the respiratory tract and that, while most contagions during the catarrhal and early weeks of the spasmodic stage, it is also contagious throughout the whole of the spasmodic stage. (2) Since about 95% of the deaths from whooping cough occur during the first five years and the great majority of these in the first two years, the most important thing is to keep babies and young children from having the disease. (3) It can be confidently predicted that when the physicians and the public understand what

whooping cough really means, when proper regulations for its control are established and enforced, and when sufficient hospital accommodations for its care are provided, whooping cough will cease to be the scourge which it now is."

MALARIA.

Malaria is another of the most prevalent of the preventable diseases. Owing to the lack of morbidity statistics relating to this disease, however, it is impossible to make a specific statement regarding its prevalence.

Rosenau states that "despite the fact that we have more exact knowledge of malaria, . . . than perhaps any other disease, despite the fact that we have accurate means of diagnosis and a ready cure, and despite the fact that we have assured measures of prevention, malaria counts its victims by the hundreds of thousands annually."

Malaria was added to the Massachusetts list of notifiable diseases last September, so that now all cases of the disease must be promptly reported by physicians to the local boards of health and all deaths from malaria are required to be reported weekly by local boards of health to the State Department of Health. We shall have soon, therefore, in Massachusetts, reliable morbidity and mortality statistics on malaria.

Among the diseases not classified in our Commonwealth as dangerous to the public health, hence notifiable to the health authorities, but claiming the attention of the public as preventable, are (1) pneumonia and (2) the venereal diseases.

PNEUMONIA.

Pneumonia is one of the most widely distributed and fatal of the acute communicable diseases. According to the U. S. census, more than 10% of all deaths in the registration area of the United States were due to pneumonia. And yet this disease now claims our attention as a *preventable* disease.

For the year 1913 there were returned to the State Department of Health of Massachusetts 6112 deaths from pneumonia and broncho-pneumonia as compared with 5965 deaths for the year 1912.

Seasonal prevalence in 1913 showed the greatest number of deaths from pneumonia in February and March and the smallest number in July and August. This shows that deaths from pneumonia occur mainly during those months when people live in closed houses. The control of pneumonia involves a careful study of the localities, including the industrial communities, and the conditions under which people live and work. The assistance of district health officers, local health officials, nurses and physicians in making such a study or survey is essential in bringing about the decrease in death rates from this disease.

VENEREAL DISEASES.

It would be difficult to mention any one disease that is of so much importance to the public welfare as the venereal diseases. The time is long since past for neglect and silence concerning them. We should institute a rational and vigorous educational campaign in order to bring into the homes ideas that cannot fail to have influence.

There is at present no method of getting accurate reports of the occurrence of cases of venereal diseases. The American Public Health Association has appointed a committee to study and report upon the problem, and the American Social Hygiene Association in New York City has been organized as a national clearing house. Dr. William F. Snow, secretary of this association, states that within the last two years important advances have been made in placing the movement on a sound basis, and that the campaign against venereal diseases has extended to such problems as the control of cancer and the promotion of mental hygiene. A number of state and city health authorities have instituted some important measures. Blaisdell quotes New York City statistics as probably representing as accurate an estimate of the amount of syphilis in a given community as any now available. During the fourteen weeks from July 4 to October 3, 1914, 25,633 infectious diseases were reported in the city of New York, with a population of a little over five and one-half millions. Syphilis stood first on the list with 6342 cases, or 28%; tuberculosis second, 5525 cases, or 21%; diphtheria third, 3370 cases, or 13%; measles fourth, 2750 cases, or 11%; and scarlet fever fifth, 1064 cases, or 4%. Blaisdell, in a study of 60 cases of fresh syphilis in the Skin Department of the Boston Dispensary, found that these 60 patients had exposed 1227 people,—134 by coitus, 442 by family or boarding house life, and 651 by occupational association. The amount of syphilis in Massachusetts today is unknown, and the only index that we have of its prevalence is from the records of hospitals and other institutions. Reports received in the Massachusetts Department of Health from 34 hospitals in the state show, for the year 1914, 4068 cases of syphilis and 3062 cases of gonorrhea.

The Boston Dispensary and some other institutions have established social service work with venereal disease cases. Michael M. Davis, Jr., director of the dispensary, believes that the reporting by public medical institutions to the State Department of Health of cases of syphilis and gonorrhea would be beneficial if properly administered. The records should not be open to public inspection and should be kept only by specified officials of the department. Davis gives three reasons why such reporting would be of value, viz.: "First, gonorrhea and syphilis can only be successfully dealt with from the public health standpoint when they are regarded as contagious diseases rather than as venereal dis-

eases; second, reporting will give the physicians, administrators, and trustees of hospitals and dispensaries a much sharper sense of responsibility for keeping their patients under treatment and for securing medical examination, and, when necessary, treatment, for the members of the patients' families who have been exposed to infection. The out-patient clinics of Boston alone receive several thousand new cases of syphilis and gonorrhea annually. That these clinics should feel their public responsibility in this matter and make it effective by proper action, as can be done in a large majority of cases without insuperable difficulty, is extremely important in the campaign against these diseases and I believe that reporting by name would be useful as a stimulus to these institutions. Third, while reporting cases merely by number would be useful because of the educational effect upon the public of the statistics gathered, and would be better than no reporting at all; reporting by name is the reasonable and ultimately necessary method, and is not open to serious objection if properly administered. E. E. Southard, commenting on a series of 6000 Wassermann tests for syphilis performed in the Harvard Neuropathological testing laboratory, states that it is clear that the percentage of outstanding syphilis is not so high as alarmists sometimes think, and that it is probably far below 23%. He gives 15% as the approximate percentage worked out for the Psychopathic Hospital intake which, he says, corresponds to the idea prevalent among dermatologists as to the general percentage in the community which they deduced from cases in skin clinics.

Southard believes the Wassermann method of diagnosing syphilis of such value to the community that a community Wassermann service might well be undertaken by a State agency. I may say that a State law with reasonable appropriation has now been enacted to enable the State Department of Health to develop such a service.

W. G. Stimpson of the United States Public Health Service reports on the treatment with salvarsan or neosalvarsan of 430 cases of syphilis, that there is no question of their great benefit to mankind. Many persons, he says, who were partially or totally disabled, have regained their health after the administration of salvarsan and have returned to work. He, however, suggests caution in using it in tertiary forms of the disease.

Frederick H. Baker, in a paper read at the January, 1915, meeting of the Massachusetts Association of Boards of Health, said in conclusion: "I should like to see appointed a committee from this association on the control of venereal diseases. I should like to see this committee, among other things, consider especially:

"1. The advisability of making syphilis and gonorrhea reportable diseases.

"2. The advisability of securing the passage of a law making these records private records.

"3. The advisability of the committee conferring with the health commissioner of this state to secure the establishment of a state Wassermann laboratory, a laboratory to which the workers in the municipal laboratories could go to improve their knowledge, and to establish a uniform technic throughout the state.

"4. The advisability of securing the passage of a law compelling public institutions to treat acute venereal disease."

Of the reportable diseases, special reference should be made to ophthalmia neonatorum and rabies; the former unprevented and untreated leading to blindness; the latter, unprevented, to a most excruciating death.

OPHTHALMIA NEONATORUM.

Ophthalmia neonatorum is a preventable disease and its prevention is a very simple matter, and yet it has been estimated that about one-fourth of all cases of blindness are due to this disease, and that the annual cost to the people of the United States to care for those who are blind from this cause is about \$7,000,000. The preventive treatment of this disease is familiar to you all,—that of cleansing the eyes of the new-born infant and dropping one or two drops of silver nitrate or argyrol solution into each eye. The state boards of health now pretty generally make such treatment available for physicians, and when it is universally employed there will be a marked reduction of blindness in children, and the country will be saved many millions of dollars.

Efforts have been made by our state physicians in Massachusetts to make sure that the infants were receiving proper medical and nursing care. Physicians have been made to account for failure to report cases of the disease. Ignorance of the law requiring such cases to be reported; ignorance of proper methods of treatment, and carelessness on the part of local boards of health, physicians, nurses, midwives and parents, have been observed. There has been noted an improved condition on the part of many boards of health and physicians as to the recognition of the seriousness of this disease and its ultimate results if neglected or improperly treated. There has been also observed an increasing tendency upon the part of some physicians, as a routine method of treating the disease when it appeared, to use the silver nitrate prophylactic provided by the State Board of Health as a preventive of this disease. In a few cases this treatment was followed by an increased activity of the inflammation. Certain physicians appeared not to consider a case as having a discharge until the eyes were literally overflowing with thick pus. The prophylactic furnished by the State Board of Health is being used more frequently. The public is fast becoming educated to the desirability of its use, and is inclined to criticize the physician for failure to use it if the eyes later become inflamed.

As the result of an energetic campaign of the State Board of Health, carried on since 1909 through the State Inspectors of Health in co-operation with the Massachusetts Commission for the Blind, the percentage of blindness due to ophthalmia neonatorum has been reduced in the state of Massachusetts at least 50%.

DOG BITE, RABIES AND PASTEUR TREATMENT.

The treatment by the Commonwealth of cases of dog bite, by dogs known to be rabid, was introduced under my supervision last summer while Acting Commissioner of Health. Cases of dog bite had been increasing in Massachusetts and many people were unable to get prompt and proper care. Persons had died from rabies without receiving the Pasteur treatment.

Since May, 1914, the State Department of Health have received notice of 212 cases of dog bite. Of this number, 68 persons were known to have been bitten by rabid dogs. Fifty-three of the 68 persons were given the Pasteur treatment by our district health physicians.

There were six fatal cases, only one of which was given the Pasteur treatment. The other five persons either did not appreciate the importance of the Pasteur treatment, or, owing to unavoidable reasons, were not reached early enough for treatment.

Arrangements were made with the Hygienic Laboratory of the Public Health Service at Washington to supply the anti-rabic virus to the State Department of Health, and in every case the virus was administered in accordance with the stipulations of the Hygienic Laboratory.

It is optional with physicians as to whether they procure anti-rabic virus from New York or elsewhere and themselves give the Pasteur treatment, or whether they desire to have the state health officers administer free the virus furnished by the United States Hygienic Laboratory.

The Washington virus, as now sent to our department, is in the form of small pieces of rabbit cord, which must be emulsified before it is used. It is hoped that in the near future the State Department of Health laboratory will make and furnish the virus in such form as to be practicable for the use of practising physicians.

Now just a word as to the protection of water supplies and the disposal of sewage; the correlation of school and community health work; improvements in housing conditions; and infant mortality and child hygiene.

WATER SUPPLIES AND SEWERAGE.

The prevention of the pollution of our domestic water supplies is an important sanitary and economic problem that receives much attention. The wastes of human life concern us especially,—feces, urine and sputum. These may enter the surface water directly in various ways.

The work of the Massachusetts State Board of

Health relating to water supplies and sewerage systems has had such a well recognized value as to need no special comment.

THE CORRELATION OF THE WORK OF SCHOOL PHYSICIANS AND LOCAL AND STATE HEALTH OFFICIALS.

It is essential that there be a thorough and well-supervised system of school health work. It is further essential that there be a practical correlation of the school and community health work.

One of the most practical questions that arises during epidemics of disease is the question, "Shall we close the schools?" In the current Bulletin of the United States Bureau of Education containing contributions from American medical journals on "The Health of School Children," Francis George Curtis concludes from his experiences "that keeping the schools open offers the best chance of safety for the scholars, both collectively and individually."

"If the schools are kept open," he says, "and the children continue in the class-rooms as usual, they are under strict observation and examined daily by the school physician, suspicious and infected cases being sent home for observation or treatment." In this way, Curtis believes, "many children are sent home before they have had an opportunity to infect others, thus reducing the probability of spreading infection. Further than this, the attention of the parents is called to the fact that the child is feeling ill and he is brought under treatment earlier."

Among some of the urgent problems of the day are those relating to (a) the medical inspection of children in rural schools, (b) the age and seasonal incidence of diseases of children, (c) the prophylaxis of measles, (d) vaccination, (e) cardiac disease in childhood, (f) tuberculous bronchial glands in children, and (g) the care of the eyes of school children. These and all such problems indicate the need of state advisory supervision of school and community health work. It would insure local supervision of the medical inspection of schools, regardless of whether that work is controlled by the school committee or the board of health; it would preserve local interest and initiative in all health work; and it would bring the state educational and health authorities together on a problem that demands combined action in the interest of the public welfare.

HOUSING CONDITIONS.

Closely allied to the study of infant mortality is the one of providing sanitary homes for the least resourceful people. The question, "What constitutes a home unfit for human habitation?" is one that health officials everywhere would do well to keep constantly in mind.

Time and again, as Kober has pointed out, it has been shown that high mortality rates have appeared hand in hand with unsanitary

and overcrowded homes. "In some cases the general death rate for large groups of population living in unsanitary dwellings amount to double or even treble what might be called the normal death rate. On the other hand the vital statistics of London show that the death rate in the improved dwellings for wage earners is far below the general mortality of the city, and the experience of housing companies in the United States, notably in Washington, D.C., is quite as gratifying."

We cannot but view with satisfaction the great developments that are taking place in municipal housing. Improvements in housing conditions and sanitation generally give rise to the best results in checking the ravages of tuberculosis and many other infectious diseases. As Thomas Gibson, of England, tersely says: "Clean houses, clean courts and streets, clean drains and clean sewers, clean water and clean food, clean air and clean bodies represent the consummation of the sanitary ideal."

INFANT MORTALITY AND CHILD HYGIENE.

Second to none in importance is the branch of public health work which reduces infant mortality. In carrying out this work we must have correct vital statistics. Unfortunately our infant mortality rates are not in general of a character which make it possible to arrange, analyze, combine and obtain proper deductions and conclusions from them in such form as will contribute most to the improvement of practical life. Some communities, however, possess statistics accurate enough to enable competent observers to draw conclusions which show results of an encouraging character.

Among the specific problems of infant mortality must be mentioned those relating to the production and distribution of clean milk, artificial versus breast-fed children, imperfect feeding and drugging of infants, married women workers in factories, maternity and factory labor, and housing conditions.

The Visiting Nurse Association of Boston did pioneer work on such prenatal care, having begun in 1901 to instruct pregnant women in suitable care and hygiene.

Emmons and others are emphasizing the fact that prenatal care is fairly to be considered a part of preventive medicine, and that the health authorities should lay plans for the prevention of death, disability and weakness from inefficient care during pregnancy and confinement. Emmons reports that Pittsburgh has recently been given \$3,000,000 to equip a maternity plant consisting of a modern hospital with local dispensaries and all the necessities for a complete service to the city.

Williams, in a study of 705 fetal deaths occurring among the white and colored races, in 10,000 consecutive admissions to the John Hopkins Hospital, found that syphilis was the most common single etiological factor concerned, in that it was accountable for 186 of the 705 deaths

26.4%. He observed that it was more frequent in the colored than in the white race, the incidence being 35% and 15%, respectively, and that it must receive important consideration in the reduction of infant mortality.

Holt and Ellen C. Babbitt in a report on 10,000 consecutive births at The Sloane Hospital for Women, New York City, state that congenital weakness and atelectasis together made up 58% of the total deaths, that still-births must be reckoned as one of the large problems in infant mortality, and that except for the larger rôle played by syphilis, the causes of still-birth in no way differ from those which produce death during the first days of life. They believe that the great number of deaths from congenital weakness can be reduced only by care of the mother during her pregnancy. The only important disease developing after birth was pneumonia. Holt says that the campaign to reduce infant mortality is essentially a campaign of education and that the two greatest agencies are: (1) the visits of the nurse to the home and (2) the attendance of the mother at the infant welfare station. In New York City, he says, there has been a reduction in infant mortality of 30% in five years and a steady fall among infants in the summer.

Knox of Baltimore states that "tuberculosis is only two-thirds as destructive for people of all ages as are the conditions which produce the high death-rate during the first year of life." He mentions three fundamental rights of infants which if allowed will save thousands of babies now born weak or prematurely. These rights or conditions are: (1) that the parents must be healthy, (2) that the mothers should be better cared for during pregnancy, and (3) that the labor must be skillfully conducted.

While many other diseases or affections might have been referred to, and many problems relating to health considered, as for example, the use and abuse of foods and drinks, habits of living and other influences on health and longevity, I have aimed to present in a general way such a number and variety of problems as are now dealt with by the majority of public health officials in communities like our own.

The so-called "new idea" of securing health and happiness through public hygiene and preventive medicine is but an awakening of the general public to the value of being taught the causes of disease with the view of removing or avoiding these causes and living without being sick.

"The public," as Lovejoy declares, "must put an end to incompetency or self-interest in its public-health service, and we submit that medical associations, state boards or departments of health, physicians, and experts in hygiene,—those who best know the facts,—must serve as pioneers in demanding that the public health department shall be elevated to its rightful place, and be made the most important arm of city, county or state government."

Health work is not a matter of merely local, but of national and international interest and importance. Local interest, however, comes first and must be maintained. The modern tendency in health administration is from local to national and international rules and regulations which insure uniformity of action. "Health work," as the Public Health Committee of the New York Academy of Medicine recently declared about quarantine work, "is essentially scientific in its nature, and cannot be carried on efficiently unless tenure of office is independent of changes in administration and of politics."

THE OPERATIVE TREATMENT OF FRACTURES.*

BY CHARLES L. SCUDDER, M.D., BOSTON.

THE presence of practitioners of both medicine and surgery at this 70th Annual Meeting of the Medical Society of the State of Ohio offers a fitting occasion for the consideration of the treatment of fractures of bone.

Several important events have profoundly influenced the treatment of fractures. The introduction of ether anesthesia in 1846 made possible painless attempts at the setting of fractures. About twenty-five years later the development of asepsis assured the safe care of compound fractures. Still twenty-five years after this the Roentgen ray demonstrated to surgeons that the supposed complete reduction of a fracture was in many cases but a caricature of reduction. And again, after twenty-five years, autogenous bone grafting is affording a sure treatment for ununited fractures.

Thus these four general factors—anesthesia, by producing painless relaxation; asepsis, by preventing infection; the x-ray by visualizing the fractured bones; and bone grafting, by stimulating the reparative process—these four factors have had a direct bearing upon the development of fracture treatment during the past seventy years.

This is not the time or place to enter upon a discussion of the technical details of fracture treatment, however much there may be of interest and of practical value in such discussion. I would call your attention rather to certain general considerations in order that we may better understand the trend of the treatment of these injuries to bone, and that we may thus arrive at conclusions which will prove helpful in establishing a better therapy.

It is unnecessary to demonstrate to this audience that the present methods of treating frac-

tures are unsatisfactory. We are aware of this fact from our own private experience. Those of us fortunate enough to be connected with hospitals where such injuries are received for treatment are convinced that this is true from our larger hospital experience.

Why are present methods of treating fractures unsatisfactory? The answer is—Because the functional results are so often poor. We all know of this from common observation.

Previous to a few years ago all fractures were treated by a non-operative expectant method. The x-ray finally disclosed that the real reason why the functional results were so poor was the faulty setting. Surgeons were not then acutely aroused by this disclosure of the x-ray. The surgical mind has been occupied during recent years with many other problems brilliant in prospect and remarkable in achievement. The study of methods for the improvement of fracture results has therefore been postponed. There has been little real interest on the part of the profession in this subject. Consequently the results have continued poor.

Certain events have directed attention to fractures. The large social movements for betterment have stumbled upon many poor results of fracture. Familiarity of the layman with x-ray plate interpretations has led the fracture patient, often improperly, to demand a better setting of the fractured bone. The admission of the x-ray plate as evidence in court has undoubtedly had a compelling influence. The Workmen's Compensation Act has directed attention to the financial loss due to fractured bone. It is necessary under the law to determine the elapsed time between the accident and the return to normal work. This time away from the earning of a living wage is the economic measure of the efficiency of fracture treatment.

The esthetic standard of the past and the perfunctory record of accomplishment must give place to the economic standard of early functional usefulness and the accurate record of events and conditions from the receipt of the injury to the resumption of full time work.

In other words, a demand has been made upon the surgeon by the laborer and the employer of labor for better results following all fractures of bone. There is today a demand arising from the surgical profession itself that more accurate and scientific work be done in this field of surgery. There is thus a demand from without and a demand from within, both of which must and will be recognized.

What are the methods available for the treating of fractures today? These methods are the non-operative and the operative.

By the non-operative treatment I understand the use of traction and counter-traction of all kinds, including Steinman's and Codivilla's nail extension, manual manipulation for reposition, massage, and fixation by splints and external apparatus. This treatment has its most faithful exponents in Professor Bardenheuer, Gräfsner

* The Oration in Surgery delivered at the annual meeting of the Ohio State Medical Association, Cincinnati, May 6, 1915.

and Schrecker of Cologne, and by J. Lucas-Championnière of Paris, and by F. Steinman of Bern, Switzerland, and by Codivilla.

By the operative treatment I understand the direct reduction of the fracture and fixation of the bone with or without foreign material through an incision in the soft parts. This treatment has been perfected by Lambotte of Antwerp, Lane of London, by Huntington, Martin, Darrach and others in America.

Professor Bardenhauer contends that an exact anatomical result is not essential for a perfect functional result. He believes that traction and counter-traction are efficient means for securing perfect adjustment of fractured bones and always a sufficiently accurate adjustment to give a functionally useful limb. His results justify his contention. His methods should be more carefully and painstakingly employed in certain fractures. Few men in this country appreciate what can be accomplished by the non-operative method, for it has not been employed consistently and persistently in any large group of cases. Professor Bardenhauer almost never operates upon a fractured bone.

Mr. Lane, on the contrary, contends that an anatomically perfect setting of a fractured bone is necessary to a functionally useful limb. Mr. Lane makes it apparent that the way to secure an anatomically perfect bone after a fracture is by operation and direct fixation of the fragments by a steel plate and screws. Mr. Lane goes to the opposite extreme from Professor Bardenhauer, and operates upon practically every fracture.

I believe everything that is good and effective in both methods should be employed in the treatment of fractures. I believe that Mr. Lane has popularized the operative treatment that its indiscriminate adoption has done enormous harm. I believe, on the other hand, that he deserves great credit for rousing the surgical world to the necessities and possibilities of the operative treatment and that he merits especial praise for his development of the technic of the operative method.

The pendulum has swung away from the traction treatment to the frequent employment of operation in fractures. Improper and unnecessary operations are being done by incompetent men. There is no more difficult operation in surgery today than a carefully conducted operation upon a fractured bone. The longer the operation is done after the fracture the harder the technical work will be. Operations upon fractured bone should only be done by surgeons of every considerable general surgical experience. The conditions under which they are done should be surgically ideal. The necessary and special instruments for precision and convenience should be at hand. If the conditions as indicated above are not present in a given case operation had best not be undertaken.

There is no time upon this occasion to enter into a discussion or description of the technical

details of the often difficult non-operative treatment, nor is there time to describe the details of the operative treatment. Each method is extremely difficult to master in its entirety. Each method is efficient under the same and diverse conditions.

This is the question that concerns us now and here: Which method, non-operative or operative, shall we employ in a given case of fracture? Where do we stand today with reference to the two extremes of treatment? In choosing between these two forms of treatment we must constantly keep in mind that the best methods of each are being compared. There are certain guiding principles which will help very much in coming to a decision.

1. The nearer to an anatomical reposition of the fragments of the fracture it is possible to come the greater will be the likelihood of securing a good functional result.

2. A primarily early operation is more desirable than a delayed operation. The results of secondary operations are unsatisfactory.

3. There is less likelihood of the non-operative treatment being successful as age advances.

4. In childhood the operative and non-operative treatment about equal each other in good results.

5. The mortality of the operative treatment is a negligible quantity.

6. Many undesirable terminal conditions will be avoided if the operative treatment is appropriately employed.

It is familiar to all of us that untreated or medically treated chronic ulcer of the stomach and duodenum may result in serious hemorrhage, in perforation of the viscus, in obstruction (pyloric), in hour-glass deformity and thus gastric obstruction, and in carcinoma. These four conditions associated with chronic ulcer are, as a rule, terminal conditions usually avoidable if surgical treatment is instituted at the proper time.

Likewise, I believe that the non-union of fractures, the malunion of fractures, infections with osteomyelitis associated with compound fractures, disabling and painful static conditions, stiff and painful joints near to fractures of the shafts of the long bones,—I believe that these are terminal conditions usually following inappropriate non-operative treatment. It is important that such terminal conditions should be avoided. I believe that the properly applied primary operative treatment will surely eliminate many of these disastrous terminal conditions.

7. The availability of either method will help to decide for or against it. If a man understands the technical details of the non-operative treatment and the operative treatment is not available, even though it be indicated, under these conditions very many fractures should be treated by the non-operative method. Good results will follow. If, on the contrary, the operative method is available and ideally possible, then the case being suited to operation, that method should be selected.

Keeping these seven general principles in the background we are confronted with a fracture. In order to decide upon a method of treatment

we must still have a knowledge of the following facts concerning the case in question:—

1. The age of the individual. Is he an infant, a child, a young adult, a middle-aged person or an old person?

2. Is the fracture open or closed (that is, in old nomenclature), compound or simple?

3. Is the fracture fresh, recent or old?

4. Is the fracture complete or partial?

5. Is the fracture transverse, oblique or comminuted?

6. What is the exact situation of the fracture in the bone? What part of the shaft is involved? Is a joint involved?

7. Are there present either local or general conditions apart from the fractured bone, which have a bearing upon the choice of treatment, such as—

(a) Injuries to other bones or to soft parts?

(b) Injuries to viscera?

(c) Is any pathology present in the body such as tuberculosis, syphilis, malignant disease, diabetes, arterio-sclerosis?

Accurate information should be had upon all these matters before treatment is chosen for a given case, that is, if the treatment is to be chosen wisely.

8. Lastly, but a very vital fact, the results of the operative and non-operative treatment must be known in all types of fracture under similar local and general conditions.

The evidence from end results is being accumulated which eventually will make it pretty nearly always possible to decide what treatment any case should receive at the outset, that is, immediately upon receipt of the injury without any experimentation.

The results studied by the Committee of the British Medical Association, and the results now being studied by a Committee of the American Surgical Association, the results of smaller groups of cases from the experience of individual surgeons, all these returns form a basis for judgment as to the relative merits of the two great methods of treatment. As the returns of treatment are more accurately and painstakingly, that is scientifically, made, present standards of judgment will change. Fractures receiving one treatment today will be more efficiently treated by another method tomorrow perhaps.

It is a long cry from the non-operative treatment of Bardenheuer and his associates to the non-operative treatment commonly employed in this country today. It is, likewise, a long way from the operative treatment of a skilled surgeon working under ideal conditions and the operative treatment commonly followed.

The best operative treatment gives good results. The best non-operative treatment gives good results. We need both forms of treatment.

The treatment of each case of fracture is a separate problem to be solved upon its own merits and according to the plan above outlined.

To take a concrete instance, I find that personally I am today operating more frequently upon fractures of the shaft of the femur, than I did formerly. I am finding that fractures in the upper third in the middle and in the lower third of the shaft, particularly in an adult, and if the line of fracture is transverse or slightly oblique,

recover with better knee and ankle joints if the long traction, made necessary by the non-operative treatment, is avoided. The restoration of the femoral shaft to its normal alignment, and the securing of the too often forgotten normal anterior curve of the femur, place the individual upon a better basis and the functional return to normal is hastened thereby.

There are certain matters of importance which should be briefly mentioned in this connection. I am very greatly impressed by the lack of interest in fractures, and the general poor treatment which fractures receive in most hospitals in this country. I am also greatly impressed by the very great desirability of properly organized and conducted practical courses in fracture treatment for practitioners of surgery, where a man may become familiar with all sides and all phases of the best methods, both operative and non-operative. Undergraduate instruction in fracture treatment must always remain elementary.

I believe that the movement toward specialization in surgery is an inevitable and normal movement. Surgery today is too large a field for one individual to master successfully. The solution of the present inadequate handling of the fracture problem is in my opinion the gradual development in each community of men particularly fitted and interested in the treatment of fractures to whom a large part of such work will be willingly delegated. These men should be general surgeons.

I believe that the large hospitals of our various cities will in time have fracture wards with continuous service, including an out-patient department, a visiting staff and house staff and nurses trained in the care of fractures. Such fracture clinics will afford ideal opportunities for instruction to undergraduates and practitioners and will also stimulate investigative work and research. Such a clinic will become a great laboratory for the study and advancement of the scientific treatment of fractures of bone.

Symposium on Endocarditis.

ENDOCARDITIS IN CHILDREN; ITS PROPHYLAXIS AND TREATMENT IN AN OUT-PATIENT DEPARTMENT.*

BY RICHARD S. EUSTIS, M.D., BOSTON.

[From the Children's Medical Department of the Massachusetts General Hospital.]

THE following paper is a preliminary report of a special heart clinic which has been conducted in the Children's Room at the Massachusetts General Hospital.

* Read before the New England Pediatric Society, April 30, 1915.

NOTE.—SYMPOSIUM ON ENDOCARDITIS IN CHILDHOOD.—These investigations represent an attempt by the Staff of the Children's Medical Department of the Massachusetts General Hospital to

sets General Hospital in the attempt to solve two problems in the treatment of early or suspected endocarditis in children. The first question is whether the strict rest in bed for weeks or months, which is almost universally advised in these cases, can be carried out from an outpatient department, and we have decided that it is possible by the use of certain methods, which will be described later. The other question is whether this prolonged period of rest is worth while, whether it actually does prevent the development, or moderate the severity, of chronic heart disease in later life, and the answer to this only time will show.

We believe that endocarditis, chorea, rheumatic fever and tonsillitis are frequently not separate entities but merely different manifestations of the same infection; that the last three are serious chiefly because of their close association with the first; that endocarditis in its earliest stages is no more surely recognizable than is incipient phthisis with a negative sputum, but that if we delay treatment until there is a definite diagnosis of endocarditis we are wasting valuable time, just as does the physician who waits for the appearance of tubercle bacilli in the sputum before sending his patient to a sanatorium. That is, treatment, in order to be effective, must be begun before the diagnosis is made, and the results of treatment are to be looked for, not in the number of "cures," but in the number of cases that can be brought through a "rheumatic" attack (using the term in its broadest sense) without permanent cardiac involvement. Hence all cases of chorea and rheumatism and those cases of tonsillitis which show any evidence of cardiac abnormality should be treated as cases of acute endocarditis and kept in bed until several weeks after the temperature and pulse have reached normal.

With the aid and interest of a number of friends, we have been enabled to make a beginning of this method of treatment in the Children's Room at the Massachusetts General Hospital. For some years we have had a sum of money at our disposal for the purpose of preventing heart disease. At first this was expended in maintaining a small "heart hospital" of ten beds, where selected cases of early endocarditis could be given intensive treatment. This will be reported on in full by Dr. J. H. Young, who was in charge. It was not entirely

satisfactory in itself, and also because it could handle only a very small proportion of the cases. The rest we treated as out-patients and, in spite of our best efforts, child after child would break loose from parental control, or the parents themselves would decide that further care was not needed, so that our results were far from satisfactory. The energy of doctors and social workers was dissipated among these old, recurrent, and comparatively speaking, hopeless cases, while at the same time many new and curable ones were allowed to become chronic through want of attention.

Beginning March 1, 1914, a special heart clinic was instituted for the home care of cases of early endocarditis. All children with rheumatic fever and chorea are referred to it and also any cases of tonsillitis which show the slightest evidence of a "rheumatic history," or any cardiac abnormality. The doctor in charge devotes two mornings a week to this clinic, seeing about ten patients a morning and spending anywhere from 5 to 30 minutes on each one. The social worker is invariably present, in the same room with the doctor and patient, in order to give the doctor the benefit of her knowledge of the home conditions and also to hear what instructions are given to the patient. The rest of her time she spends in visiting the members of the clinic in their homes, helping and encouraging the parents to follow the directions, bringing toys and games for the children to play with or books for them to read, and making herself generally helpful. She also, although not a trained nurse, records the temperature and pulse rate at each home visit, and reports frequently to the doctor the condition of the children and obtains his advice without bringing them to the clinic too often.

After the medical history and physical examination of a new case are over, the doctor spends considerable time explaining the nature of the trouble to the mother, emphasizing the imperative necessity of immediate rest in bed and endeavoring to get her intelligent cooperation. Severe cases, and cases in which home conditions are very poor are given ward treatment at once; with the others a strong effort is made to carry out the treatment at home. Careful directions are given the mother and repeated until she understands them. If possible the social worker visits that very afternoon, or certainly the next day, and thereafter as often as the individual case seems to demand. In some cases she visits almost daily at first; in others once a week suffices, the important point being to keep the child in bed and quiet. With this close supervision it is possible to let the child go two or three weeks before asking for another outpatient visit. Any complications or unusual symptoms are reported to the doctor and he decides whether or not the child should be brought in at once for examination.

Subsequent visits to the hospital are made as often as each individual case requires. New

termine the best way to handle endocarditis in childhood. Our experience has shown that the treatment of endocarditis, when compensation is broken, is merely palliative. Further study leads us to believe that in a large number of instances heart disease in the adult originates in childhood. We, therefore, have put our energies into the treatment of endocarditis during the early stages. During the course of our studies many physical facts have been brought to light, one of which has already been reported by Dr. Gilbert. Boston Med. and Surg. Jour., clix, No. 3, p. 55). This first report is made not because it is complete but because we feel that a definite advance has been made in the early treatment of endocarditis in children. We feel that in such treatment lies the only hope of a complete cure; and while we realize that we have been studying the problem for too short a time to make any authoritative statement, we feel that in many instances we have obtained permanent cures and that it is only with early treatment that one can expect lasting results.—FRITZ B. TALBOT, M.D.

patients usually return in about two weeks, others once a month, and the convalescents only three or four times a year. Too frequent visits to the hospital defeat their own end by exciting and overtiring the patient; if they are allowed to wait too long between visits they are likely gradually to break free from restraint, to develop an unexpected endocarditis, or on the other hand even to overdo the bed treatment; each case must be handled as an individual and it is just here that the help of the social worker is invaluable.

After the chorea or rheumatism is over and the pulse and temperature have been normal for several weeks, we begin to allow them to get up. There have been a few children in whom a rapid pulse persisted without other signs of endocarditis, until in despair they were allowed out of bed. Then, rather to our surprise, the rate slowed down to normal; so this possibility, of too long a stay in bed, must be kept in mind.

The process of getting the children out of bed and back to a normal life is long and slow. We begin by allowing them to move into a chair for one-half to one hour a day and report in a week either personally or through a social worker. If all goes well and the pulse rate remains within reasonable limits, the time out of bed is extended hour by hour, with some children quite rapidly, with others very slowly and with great caution, until they are up all day except for an after-dinner nap. When they are first out of bed they are kept playing quietly in the house or on the piazza; then they are allowed on the street, at first only with an older person or at the time when the other children are at school and finally are sent back to school again themselves, beginning with only one session a day so that the afternoon nap may be continued. If they are then doing well all restraint is removed and they are encouraged to lead normal lives although the great majority are still kept under observation and required to report two or three times a year.

This is our ideal standard. In practice we do not expect the impossible. Nevertheless, considering the average type of parent with whom we are dealing, our advice is surprisingly well followed. The fact that the doctor is willing to spend 10 or 20, occasionally even 30, minutes in talking with them, and the frequent friendly visits of the social worker, make an impression that was wholly lacking under the old regime with its hurried, impersonal, and half understood directions. The following figures illustrate the results we have obtained.

Bed Care. Thirty-four cases entering after March 1 were sick enough to require full time rest in bed. Seven of these were discharged from the clinic for various reasons before the completion of the treatment and five more are still in bed, which leaves 22 cases whose completed rest in bed averaged 7½ weeks apiece.

Under Restraint. By this term is meant that the children were kept out of school or were sent

only for a half day, were not allowed to play hard, and were made to lie down for two hours a day. Fifty-three cases come under this heading, the other 7 being kept under observation, but not under restraint. Excluding 1 case that died of malignant endocarditis and 9 that were discharged before treatment was finished, we have 43 cases. Of these, 10 cases under restraint on March 1 have been kept under restraint since then for periods of from two to nine months—an average of four months. Eighteen cases still under restraint Dec. 1 have been kept under restraint for periods of from one-half to nine months, an average of three months. Fifteen cases begun and concluded between March 1 and Dec. 1, these, of course, being the lightest ones, were kept under restraint for periods of from one-half to seven months—an average of three and one-half months.

One feature of the heart clinic that must be emphasized is its necessarily close connection with other institutions and organizations dealing with such children. Reference has been made already to the ward care of severe cases at the Massachusetts General Hospital. Before they are discharged, our social worker has made everything ready for them at home and explained that their return from the hospital does not mean that they are well, but merely that they are better, and that it is still necessary to stay in bed until the doctor in the Out-Patient Department gives permission to get up. In this way we feel that their hospital stay can be somewhat shortened and yet relapses prevented.

Other children are taken care of at the Brookline Heart Hospital, and then returned again to us.

Others again, in the summer, go to Children's Island at Marblehead, where special arrangements have been made to give them bed care.

However, we feel that, except for acutely sick children, an institution is not the ideal spot. It is a question not only of relieving the immediate symptoms, but of preventing relapses. A child discharged practically well from an institution goes back to the same environment in which it became sick, and with the child appearing perfectly well it is almost impossible to persuade the parents to make any changes. However, if the child has been at home from the first, there is more chance of the necessary improvements being made. The choreic girl, for instance, will be given a bed of her own, instead of sleeping with several sisters, and the custom once started is more likely to persist. Having been in bed at home for a month or so she is more willing to keep on taking a nap and going to bed early, and there is not the sudden and exciting total change of environment that so frequently upsets a choreic child on returning home from a hospital. Similar arguments apply to cases of early chronic endocarditis, and even to children who have had rheumatism without cardiac involvement.

Hence, when for one reason or another, home

treatment was unsuccessful, we adopted the expedient of boarding the sick children out in other families. We started with one or two, rather exceptional cases and have found them to do so well that we are sending others. There is one girl in particular who has been in the ward several times with chorea and has always relapsed on returning home, who is now doing well boarded out and will probably soon be able to go back to school.

So far we have worked with four different organizations, The Children's Aid Society, The Children's Mission, The Children's Friend Society and The Society for the Care of Girls, each of which has taken one or more of our patients and assumed responsibility for them while they are away from home; and without their assistance we should be totally unable to carry out a method which is proving of the greatest value.

At the time the figures were collected for this paper the heart clinic had been in operation just nine months—from March 1 to December 1, 1914,—and hence this is merely a preliminary report.

A total of 60 cases have been treated; 20 of these were old cases that still needed supervision, and were taken on in a body on March 1. Twenty-three cases have been discharged during the nine months, leaving 37 cases still under supervision.

Etiology. Thirty-two of the 60 cases, or 53.3%, were choreic at the time of admission, and 10 more gave a history of choreic attacks in the past, making a total of 42 cases, or 70%, in which chorea played a part. Nine cases, 15%, were rheumatic on admission and 19 more gave a history of joint or muscle involvement in the past that was interpreted as of rheumatic origin, making a total of 28 cases, 46.6%, which were classed as rheumatic. Thirteen cases, or 21.6%, gave a history of both rheumatism and chorea, and in two of these both diseases were active at the same time while the patient was under our observation. In only one patient was there no evidence of either rheumatism or of chorea, he being a boy who was under observation for a suspected endocarditis following tonsillectomy.

We have endeavored to classify the cases according to the condition of the heart at the time of admission and again at discharge, but have found it exceedingly difficult because of the nature of the disease. It is fairly easy to say in a given case, where the heart shows no enlargement, no increase in rate or change in rhythm beyond a simple sinus arrhythmia, where the sounds are of good quality and there is no murmur, that that patient has no endocarditis. The other extreme is also comparatively simple, but how are we to classify the intermediate stages? It is virtually impossible by any of our present means. Hence, for the purposes of this paper only, we have made a large group with the heading "heart suspicious" and included in it those cases which showed some but not all the signs of acute endocarditis. The following figures there-

fore, while suggestive, are not to be relied on absolutely, and for the ultimate test of whether our efforts are worth while we must wait several years to compare the incidence of chronic endocarditis in our clinic with similar cases which have not had the same intensive treatment.

Nineteen cases had normal hearts when first seen. Sixteen of these are still normal; 2 are classed as "suspicious" and are still under treatment; 1 has a definite endocarditis and is still under treatment.

Twenty-five were called "suspicious" on admission; 17 are now normal; 6 "suspicious"; and 2 have a definite though slight chronic endocarditis.

Adding these two groups together, *i.e.* all that did not have a definite endocarditis when they were first seen, we have 44 cases, only 3 of which (6.8%) have developed a definite endocarditis while under our care. Eight more (18%) are classed as "suspicious."

We now come to the 16 cases which did have a definite endocarditis when they were first seen. Eleven of these were chronic from the first or had a slight acute endocarditis on an old chronic lesion; none of these have grown worse while under observation. The 5 remaining cases were acute from the start; one was the malignant type, developed a progressive carditis, and died; another, in spite of good home care and strict rest in bed, ran a persistent high pulse with occasional fever, and now has a severe chronic mitral regurgitation; two give evidence of slight perfectly compensated mitral regurgitation; and one, which in the ward was thought to have adhesive pericarditis now shows no evidence of abnormality by physical examination or by electrocardiogram.

To sum up: we have treated 60 cases of chorea, rheumatism or early endocarditis for varying lengths of time from ten days to nine months. Eleven had chronic endocarditis when first seen and were carried through their chorea or rheumatism without further cardiac involvement. For the purpose of the following table, *i.e.* the determination of the incidence of fresh endocarditis while under efficient treatment, these cases can justifiably be classed as "normal hearts."

1 has died of malignant endocarditis.....	3.33%	} 24.99%
1 is a hopeless cardiac cripple.....	8.33%	
5 developed chronic endocarditis but are well compensated.....	8.33%	
8 have "suspicious" endocarditis.....	13.33%	
34 have normal hearts.....	56.66%	} 74.99%
11 have chronic endocarditis antedating their admission to heart clinic.....	18.33%	

Thus 75% came through their attack without acute endocarditis, 13% more are still in the suspicious class, and only 12% have received permanent cardiac damage. However it must be remembered that these are merely provisional figures obtained from a nine months' study, that they deal usually with but a single attack, and

that some of the cases that we now consider to have normal hearts may later show cicatricial changes that have escaped observation.

Relapses. A total of 9 patients came down with a relapse while under treatment and in only 2 of these can it truthfully be said that they were not following our directions. The other 7 were following the instructions fairly well and had evidently been allowed to go ahead too fast. Two of the relapses were distinctly initiated by tonsillectomy, one a chorea, the other an arthritis. We also have records of another case before this clinic was started, where a severe relapse of chorea followed immediately after the extraction of several teeth. On the other hand, tonsils were removed in three other cases with beneficial results. Our present opinion is that tonsils and adenoids should be removed and teeth treated by a dentist in all cases of "rheumatic infection" which give a history of repeated sore throats, or head colds, or of toothaches, or in which anything abnormal can be discovered on examination; but that treatment should preferably be postponed until the child is over his chorea or rheumatism. If, however, the disease is at a standstill or growing worse in spite of good treatment, we advise immediate interference. The wholesale removal of tonsils and adenoids in the course of or immediately following chorea or rheumatism we regard as unnecessary or even dangerous.

The following figures may be of interest as showing the relatively small number of children which had to be sent to an institution.

Ward Care. Twelve cases were admitted to our wards for periods of two weeks to four months.

Brookline Heart Hospital. Three cases were sent to this special home; 1 was discharged in two weeks because of vaginitis; the other 2 are still there after two and three months respectively.

Children's Island. Two cases were sent to Marblehead; 1 returned after one month with a severe relapse, and was admitted to our ward; the other stayed three months and was greatly benefited.

Home Care. One patient is in the hospital. The others have all been taken care of at home for periods varying between ten days and nine months, and 48 of the 60 children have been treated at home from beginning to end.

Boarding Out. Up to December 1 only 3 patients had been boarded out, for periods of two and one-half to five months. They have done very well, and we feel that it is a method to be used more and more in persistent choreas of moderate or slight severity, where the home surroundings are a factor in keeping up the disease. However, it is not to be used as a temporary measure, but only on the distinct understanding that the child is to stay away for several months after he is well; otherwise he is only too apt to relapse. Also it is necessary that the

boarding home be a good one with few or no children, and that the woman be intelligent and under close supervision.

In conclusion we consider that we have shown that it is possible by means of a special clinic and a full time social worker to give efficient treatment for early or threatened endocarditis to patients of the out-patient class. According to the estimates in the literature the incidence of endocarditis in the "rheumatic infections" varies from 40%-80%; in our series so far it is certainly not over 25%, and perhaps less. Whether these results are permanent or not it is impossible to say at present, although we hope to supplement this preliminary report a few years hence with an account of the end results of these cases.

SOCIAL PROBLEMS INVOLVED IN THE TREATMENT OF CHILDREN WITH HEART DISEASE, FROM THE POINT OF VIEW OF AN OUT-PATIENT DEPARTMENT.

By CLARA M. WELSH, BOSTON.

[From the Children's Medical Department, Massachusetts General Hospital.]

THERE has always been an attitude of pessimism among physicians with regard to the prognosis of heart disease in children dependent upon dispensaries and hospital clinics for their medical treatment. This has not been wholly because of the nature of the disease, for a great many people lead practically normal lives though suffering from a heart lesion. Neither is it because the children receive inferior medical treatment in dispensaries and out-patient clinics, for the physicians of the poor are the physicians of the rich in a great many instances, and the child who attends a hospital clinic is treated by the same physician as his up-town brother.

Having made a survey of the types of cases treated in the Children's Clinic for three months, and having found that the third largest group treated in the clinic was suffering from some form of a rheumatic infection, or its results, Dr. Talbot attempted to analyze this attitude of pessimism amongst physicians and arrived at the following conclusions. Heart disease is a social disease, and needs social treatment. The child and his family must be educated, his environment must be altered, and adapted to his limitations. He must be kept under supervision for a long period of time, not merely until he has recovered from the acute symptoms which bother him, and which have made his family recognize the immediate necessity of a physician's care.

And so, in January, 1911, a social worker was employed to help in the treatment of this large and interesting group of children. Her problem has been to make a social investigation of all children falling within the rheumatic group, *i.e.* endocarditis (chronic and acute) chorea, and rheumatic fever; to bring to the physicians the information obtained from this investigation, which had bearing upon the child's treatment; to form, with him, a plan for treatment suited to the individual case; to see that the child's parents were instructed and educated regarding his condition; to help adapt his environment to his needs, in so far as possible; and to see that his connection with the hospital was not lost, but that he reported for observation as often as necessary.

The observations recorded in this paper cover the experience of these four years, in working with 264 children. Some have been under supervision during the whole time, and the group has been constantly added to; 8 have died; 2 have been placed in homes for incurables; 23 are having bed care; 32 are still under restraint; 120 are leading practically normal lives, happier and healthier for the knowledge of how to live in spite of their handicap, and how to prevent it from becoming more serious; 10 have been graduated to the adult medical clinics; 69 have become inactive.*

It has been the custom in the Children's Clinic for the physicians to automatically refer all cases of heart disease to the social worker. If the patient is to go to the wards for treatment she makes her investigation while he is there, and has a plan for convalescence ready on his discharge. If he is to be treated in the outpatient department only, he is given an appointment to return. Before it is time for him to return the social worker has made the investigation which is of benefit in making further plans for the patient's treatment.

It is absolutely essential for the social worker to have as much medical knowledge about the child's condition as the physician can give her. It is not sufficient for her to know that the child has a "damaged heart." She must know something of the degree of damage, how much the function is impaired, if possible, whether any acute process is going on, and the exact amount of rest and exercise which the physician prescribes. The whole future of the child may depend upon the exactness of her knowledge, and the accuracy and vividness with which she interprets it to the child's family. It is her responsibility to arrange for these directions to be carried out so far as possible, and her report of the child's behavior between visits serves as a partial basis for further treatment and instructions.

From the point of view of treatment, social as well as medical, heart cases divide themselves into two groups, acute and chronic. A great

many of the cases in the acute group in time pass into the chronic group. Our method of treatment of acute cases, absolute rest in bed for a long period of time, involves many social problems. Few hospitals for treating acute illness can keep patients suffering from acute endocarditis for as long a time as bed care is required. Obviously, some provision must be made for these children, outside the hospital, if treatment is to be lasting and effective.

Since the beginning of our work we have cared for many of these children in their homes. At first, owing to bad home conditions, or the children being unruly, we felt the need of a convalescent hospital where patients could receive bed care for as long a time as necessary. Such a hospital was opened in December, 1911, and continued until March, 1914. During that time we cared for 54 children at an expense of \$2,696.81. The parents of these children paid what they could, and the balance was raised from private funds. Our accounts show that about half of the total amount had to be raised from others than parents.

The group of children cared for at this convalescent hospital makes an interesting study from a medical point of view. There are also some interesting social facts gathered from a study of the individual cases. All of the patients, with a very few exceptions, went from the Massachusetts General Hospital, and were sent, because, in the opinion of the physician and social worker, they could not be cared for at home under existing conditions. The social worker kept in touch with the progress of the children while they were there. They were not discharged without her knowledge and approval, and were under her supervision when returned to their homes.

Some of the social worker's most difficult problems have come at this point. The child has forgotten how to adjust itself to family life, for a long period spent in an institution, however home-like, sometimes destroys relationships which may have to be painfully rebuilt. It seems practically impossible for a mother or father of somewhat limited experience and knowledge, to understand that this child, who is returned to them apparently looking and feeling so well, must do and refrain from doing, certain things, in order to continue looking and feeling well. The parents have not experienced the long, tedious period of bringing their child back to health. The child himself forgets quickly, and the process of educating parents and adjusting child to environment must begin anew.

Probably a greater improvement is made in a short time by this method where the conditions can be absolutely controlled, than when an effort is made to educate parents to care for a child at home. But what happens in the long run? Often it is necessary to sacrifice the child and allow the unbelieving parents to go their own way, learning by experience when the child has a relapse, before the process of education can

* Referred to other hospitals, discharged because of lack of cooperation. Moved from town, or lost track of.

really begin to take root. This method surely involves much waste. The expense is great, and little can be accomplished.

After two years of experiment with convalescent hospital care, we began to see that the few children whom we had been able to care for adequately at home, did better in the long run than those who were sent to the convalescent hospital. There were fewer relapses, the treatment had more continuity when relapses came and the parents were prepared to meet and care for these as they occurred.

The number of cases under intensive supervision had to be limited because of pressure of work on the part of the social worker. We found that at the same expense required to care for ten children in the convalescent home, we could employ a visitor who could supervise from 30 to 40 children in their own homes, visiting as frequently as required, and making the necessary social adjustments in the family. In April, 1913, a committee had been formed to raise money for helping to care for children at the convalescent home. This committee generously offered to use their funds to pay a visitor's salary, and to continue as an advisory body to whom she should report progress with the children under her supervision. The results of nine months of this work are reported on elsewhere by Dr. Richard Eustis.

This visitor has under her supervision only children with acute heart disease, or those in danger of developing it through chorea or rheumatism. If the home is unfit, it is her business to find out the causes of this unfitness, and if possible, to remedy them. Poverty alone is no reason for removing a child from its parents. It is better to aid the family to keep the child, than to aid them by removing him.

The process of educating more or less ignorant parents, and a young, heedless child, is a slow, patience-demanding one. But much can be done by frequent visiting, explaining and persuading, on the part of a hopeful, persistent and resourceful person. She must understand children and must have at her disposal all kinds of ways and means for keeping the child happy and contented in bed. She must be able to teach the parents how to keep him comfortable there, and to realize the importance of following the doctor's instructions to the letter. The economic advice of, "Follow the doctor's instructions, and have the child improve rapidly. Don't follow them, and have a sick child for a long time," usually appeals to parents.

There are certain medical facts which the visitor must know, certain symptoms which she must be able to recognize and report to the physician. But her function is that of a visiting teacher, rather than that of a visiting nurse. She must have a knowledge of the resources of the community, charitable, social and educational, in order that the needs of her families may be recognized and met.

I know of only five reasons which make it justifiable and necessary to care for a child with heart disease outside of his home. First, when there is present a condition needing constant medical and nursing care. The solution here is, of course, hospital care. Second, when other illness in the family, usually that of the mother, makes home care impracticable. Third, when there is a large family of young children in a small home, so that anything like rest and quiet is impossible to attain. Fourth, when there is persisting ignorance and lack of coöperation on the part of parents. Fifth, actual criminal neglect on the part of parents who are able to bear the burden.
